APPLICATION FOR ENDORSEMENT BY THE MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.

Of Certificate of Registration or License to practise Medicine and Surgery in the State of ..... issued by the ..... Mo. ..... day ..... year. ..... .

I hereby apply for certificate of registration to practice Medicine and Surgery in the State of Michigan, and submit the following proofs, as required by Michigan Act. 237, Laws 1899.

1 Name .....
(write name in full, including middle name)
P O Address ..... Date .....
2 Place and date of birth ..... Age.....
3 Present residence ..... 4. Intended residence. .....
5 **Preliminary Education.**

Name and location of Institution attended	Have you fulfilled the minimum requirements of Preliminary Education as recorded on page 4 of this application? Ans..... (yes or no)

Academic degree of ..... received from ..... 19....

6. **Medical Education.**

Name and Location of Institution attended	Have you fulfilled the minimum requirements of Medical Education as recorded on page 4 of this application? Ans..... (yes or no)

Degree of Doctor of Medicine received from .....
at 19
..... M D., Applicant.

7 **Certificate of Medical Examination.**

It is hereby certified that ..... holding ..... as evidence of Preliminary Education, on the ..... day of ..... 1 ....., received from ..... a diploma conferring upon him the degree of doctor of medicine and that he previously studied medicine at least ..... full years, including ..... regular courses of lectures in different years, as follows:

Month	Year	Month.	Year	Name of Institution
	1	to	1	
	1	to....	1	
	1	to	1	
	1	to	1	
	1	to	1	
	1	to	1	

and that he has fulfilled the maximum requirements of Preliminary and Medical Education as recorded on page 4 of this application.

Dated at ..... 19 .....
Signature of Pres., Dean or Sec'y

.....
Name of College.

(SEAL)
The seal of the Institution must be affixed

No. 8. Certified Copy of State License or Certificate.

(A verbatim copy to follow here over seal of State License Board, certified by the Secretary thereof.)

9. **Certificate of Secretary:**

I ..... of .....
Secretary of ..... certify that the original of the preceding certified copy of State License or Certificate No. ..... was issued to Dr ..... of ..... in ..... 19.... upon obtaining at least a general average of 75 per cent after an examination by this board in the following branches Anatomy Physiology Therapeutics, Toxicology, Histology, Hygiene Public Health Laws, Practice of Medicine Surgery Obstetrics, Gynecology, Diseases of the Eye and Ear Bacteriology and Medical Jurisprudence

..... M D.
(SEAL) Secretary.
Affix seal.

10. **Affidavit of Applicant:**

STATE OF ..... } ss
County of ..... } ..... of .....

being duly sworn, says that ..... is the person referred to in the above application for license to practise Medicine and Surgery in the State of Michigan, that he has studied medicine four years, including four courses of lectures of not less than six months in each year, in different years, and the beginning of the fourth or final six months of such course dated from October preceding the year of the final examinations for the degree of M D., and that all the statements herein contained respecting age, residence, academic and medical education and State Examination and license are each and all strictly true in every respect.

Sworn to before me this
day of 19

..... M.D.
Applicant.

A Contribution to the Biology of the Meningococcus.—P Sorgente, from the results of his studies, holds that the diplococcus, isolated and cultivated from the nasal cavities and the ears, was the agent of infection in the cerebrospinal meningitis of a child The nasal and auditory canals are the most frequent channels of infection in this disease. The diplococcus, isolated from the nose and kept for three months in cephalo-rachidian fluid, acquired characteristics very similar to those of the meningococcus isolated from the liquid of the cerebral ventricles, whence the author concludes that the properties described as peculiar to the meningococcus of Weichselbaum are, probably, due to the influence of the cephalorachidian fluid.—*Il Policlinico*

EPIDEMIC POLIOMYELITIS, WITH A REPORT OF TEN CASES.*

By D. H. MacKENZIE, M.D.,
MABBETTSVILLE, N. Y.

I ASK attention in this paper to the consideration of an acute form of disease, seemingly infectious and of bacterial origin, presenting in its initial stages the clinical features of an acute germ invasion, quickly followed by atrophic paralysis of associated muscle groups, in one or more extremities. Instances of its seeming epidemic, or rather endemic occurrence have been reported, the most noted examples in North America being an irruption of poliomyelitis reported by J. J. Putnam, which occurred in and near Boston in 1894, and the outbreak in Vermont during the same year, reported by Dr. Dana of New York. The last mentioned is said to be the most remarkable instance of epidemic poliomyelitis on record. The cases, some 160 in number, appeared from June to September, in the towns and country lying in the valley of Otto Creek. Most of the cases occurred in children, although several adults were attacked, and one man, aged seventy, had a typical case. Domestic animals, such as fowls, horses, and dogs, also suffered from the malady.

A somewhat similar outbreak occurred in Dutchess County, N. Y., during the summer and autumn of 1899. There were in this instance some thirty cases, confined to an area of country ten miles in diameter, lying to the east of the city of Poughkeepsie. In this epidemic adults were attacked as well as children, and all of the fatal cases were those of adults, or at least those over twelve years of age. The ten cases which came under my care I will describe in the order of their occurrence.

CASE I.—Young man, aged twenty-three years, healthy and well nourished; without discoverable cause, was taken ill whilst engaged in lumbering. He came home on Friday night complaining of pain in the back and legs. This condition continued on Saturday. Sunday he had retention of urine, when I saw him for the first time. At that time his back and legs were less painful, and gave the sensation of being asleep. He had a temperature of 103°, was restless with a furred tongue, and some gastric disturbance. He was unable to move the right leg, the left he could flex slightly toward the body. Tuesday the paralysis extended to the arms. After this, phonation, deglutition, and respiration became affected, and he died on Saturday, nine days after he came home.

CASE II.—Colored girl, aged fifteen years; previously well and strong; was taken with fever and pain in the neck and right arm. In five days the fever subsided and the right arm was found to be paralyzed, also the right leg partially so. She was able to sit up in about two weeks, but was not able to walk or move her right arm for three months. From that time the legs began to grow stronger, the right being slightly atrophied. At the present time there is no atrophy of the muscles of the leg, and she can walk as well as usual. She has not fully recovered the use of the right arm. The muscles around the shoulder and upper part of the arm are atrophied, and the right biceps is only about two-thirds the size of left. In other respects she is perfectly well.

CASE III.—Young man, aged twenty-one years, college student of previous good health; without any apparent cause was taken with fever, but no pain or tenderness in any part of the spine. However, he was restless, and kept moving his arms and legs about uneasily. Next day he had confusion of ideas. Part of the time he thought he was back in college. He had also photophobia and slight strabismus. The fever subsided in ten days. Convalescence was slow, it being about four weeks before he could sit up. When he tried to walk, the toe of right foot would drop. Three months afterward I found that the muscles of the left side of the face were shrunken, and at that time the right leg was one inch smaller than the left. At the present time there is scarcely any difference in size, and there is no toe-drop. The muscles of the face are very much improved. The man's mind is strong and vigorous as before, and he appears to be fully recovered.

---

*Read before the Dutchess County Medical Society July 9, 1902.

Case IV. The day I was first called to see the case I have just described, I also prescribed for a younger brother, twelve years old, who had a slight fever, and appeared to be developing some form of malaria. The next day he complained of pain and stiffness in neck and back, and began to have weakness in the legs, both legs being equally affected. The day following paralysis was more pronounced and was extending upward, the arms showing a gradual weakness. On the two succeeding days there was a gradual extension of the paralysis, which finally affected the muscles of respiration. His general appearance at any time would not indicate that his condition was serious, and he was able to converse intelligently up to the time of his death. After the second day he complained of no pain and seemed unconcerned, though apparently conscious of the approaching end. Death was due to paralysis of the muscles of inspiration. The condition might be illustrated and not overdrawn by comparing it to a man caught in a quicksand, where hour after hour he sinks deeper and deeper in the slough, until finally he disappears altogether.

Case V.—Colored girl, aged fifteen years, was taken with fever, pain, and stiffness in the neck, and pain in the left arm. The fever rose to 103°, but dropped to 100° in forty-eight hours. There was slight fever for three days longer, during which time the pain and stiffness disappeared, and there remained a partial paralysis of the left arm and leg. Six months afterward there was some atrophy of the leg, also toe-drop. At the present time she walks as well as ever, and there is no atrophy in arm or leg.

Case VI.—Boy, six years old, was taken on Friday evening with fever, pain in neck, arms, and legs. I did not see him until Monday. The temperature was then 99°, there was pain in the neck, but none in arms or legs, and there was loss of muscular strength on the left side. In two weeks he could walk as well as usual, and has been well ever since.

Case VII.—Girl, seven years old, was taken with acute symptoms similar to the others. Next day there was inequality of the pupils, and she was very uneasy. She recovered with loss of muscular strength on the right side. Three months afterward she was improved, but would trip easily when walking. Her parents left the town soon afterward, and I have not heard from her since.

Case VIII.—Child, two years old, had been ill for three days when I saw her. The mother said that she did not notice anything about the child, except that she had been feverish for a few days, and on the morning that I saw her she discovered that the arm and leg of the left side were paralyzed. At the present time there is partial loss of motion and decided atrophy of the leg.

Case IX.—Girl, eight years old, began with symptoms similar to the others. She recovered with weakness in the right leg, which continued for about ten days, then began to improve, and she was apparently well in four weeks.

Case X.—Young man, thirty-five years old, of healthy appearance and strictly temperate habits, was taken on Sunday morning. I saw him in the afternoon. He had been around all day, but said that he felt uneasy, and had an aching sensation in his back. Temperature 102°, pulse 95. Next morning his condition was about the same as the day before and he remained in bed During the day he had retention of urine, which was relieved. About ten o'clock in the evening he said he felt better and slept for a short time; when he awoke he breathed with difficulty, and also complained of weakness in his legs. At midnight his condition was quite serious, respiration 56, pulse 120, but regular. There was no respiratory motion whatever in the chest, and only a faint respiratory sound could be heard. There did not appear to be any obstruction in the breathing, only a mechanical inability to expand the chest. The muscles of inspiration grew steadily weaker, and the man died at four o'clock Tuesday morning, being about six hours after the muscles of respiration became affected. He was able to talk intelligently up to the time of his death.

These cases occurred in the town of Washington. There were also five other cases in the town. To describe them would only be a repetition of the preceding reports. Three proved fatal, and in each case the paralysis began in the lower extremities, and extended upward until the muscles of respiration became affected. The other two recovered, one with muscular weakness in the right side, but was entirely recovered in six months, the other with flaccid paralysis of the left leg, which at the present time is atrophied and partially paralyzed. There were also two cases in the town of Amenia, with one death. This makes seventeen cases in the towns of Washington and Amenia, with seven deaths, or a mortality of over 41 per cent.

Of these seventeen cases only two presented the classical symptoms of poliomyelitis. One case in Amenia was, undoubtedly, cerebrospinal meningitis, having the convulsions, coma, and other symptoms peculiar to that disease, and was diagnosed as such by the attending physician. Now the question arises: What was the disease in the other fourteen cases? Dr. Bondurant of Mobile, Ala., who has written several articles on this and kindred subjects, in his comment on the Vermont outbreak of 1894, says: "The clinical histories of the majority of the cases were typical of poliomyelitis, but some of them presented the features of peripheral neuritis, while many of the fatal cases exhibited the convulsions, coma, and other symptoms of cerebrospinal meningitis. We have then presented to us the interesting fact that during the same epidemic, and presumably from the same cause, there occurred cases of poliomyelitis, neuritis, and cerebrospinal meningitis, a circumstance lending color to the contention of Auerbach, that these several forms of nervous disease may result from the same microbic infection. It is also noteworthy that during this epidemic mild cases of poliomyelitis terminated in complete recovery, although a study of the reported cases of recovery convinces me that some of them were instances of multiple neuritis rather than of poliomyelitis."

Two of the fatal cases which I have mentioned were diagnosed as Landry's paralysis, and this diagnosis was afterward sanctioned by some of the local physicians. Dr. W. B. Pritchard of New York, in an article in Sajou's Encyclopedia, makes the statement that "Landry's paralysis is quite probably a special form of multiple neuritis." Zusch of Groesbreitenbach also evolves the following conclusions: "Landry's paralysis must no doubt be considered an acute intoxication paralysis. Concerning the cause we have so far no fixed indications; however, it does not seem to be a single factor. In the majority of cases the initial point of the lesion appears to be in the peripheral nervous system."

Now, from the fact that most of the cases were those of adults, from the pain, tenderness, and parasthæsia of the early symptoms, and the fact that the paralysis extended from below upward, and also that all the cases which did not prove fatal in the acute stage, except two, fully recovered, we may conclude that a large percentage of the cases was probably of multiple neuritis.

It would also seem that during this epidemic there occurred cases of poliomyelitis, cerebrospinal meningitis, and multiple neuritis, and if the contention of Auerbach be correct, we may infer that they all arose from the same cause, and from the same microbic infection.

Since writing the above, I have read with great interest the article of Dr. W. B. Pritchard in the Medical Record of July 26, 1902, entitled "A Classical Example of Landry's Paralysis," particularly because it describes very minutely and exactly at least two of the fatal cases in the epidemic of 1899.

DISCUSSION OF THE REPORT ON YELLOW FEVER ON THE U. S. SHIP "PLYMOUTH" IN 1878 AND 1879.

By W. C. GORGAS, M.D.,
MAJOR, MEDICAL CORPS, U. S. ARMY.

This instance of yellow fever, recurring on a ship some months after the disappearance of the disease, and after the ship had been exposed to the cold of a Boston winter, and carefully disinfected, is more frequently referred to than any other example in the history of yellow fever, as one in which the disease could not have been perpetuated and transmitted by the mosquito. I go into the discussion in reply to quite a number of inquiries on the subject, but more particularly in reply to a letter from Dr. Stanford E. Chaillé of New Orleans, La. I know of no higher authority on the subject of yellow fever than Dr. Chaillé, and any objections urged by him against the theory that "The stegomyia mosquito is the only means of transmitting yellow fever from man to man" should receive due consideration and careful thought from its advocates. Dr. Chaillé writes as follows:

> "But I write to you largely because I am by no means satisfied that this is the sole means of propagation. This mosquito theory fails to explain the facts recorded in the case of the U. S. S. *Plymouth*, in 1878–'9, and in some other outbreaks at sea recorded by La Roche, etc.
>
> "The Surgeon-General, U. S. N., issued, in 1880, a 'Report of Yellow Fever in the U. S. S. *Plymouth* in 1878–'9.' If you have not that report I hope you will get it, and then if you can explain the facts consistently with the sole propagation of yellow fever by mosquitos, I am sure you would effect a good work by publishing your explanation."

The whole question of yellow fever and malaria, and the relation of the two diseases, comes up with renewed interest at this time, in connection with the Panama Canal. The one great difficulty heretofore in the work on the Isthmus of Panama, both in the Panama railroad, which was finished in 1855, and in the De Lesseps canal, which was worked on between the years 1880—'90, has been the health of those employed in this work. The deaths in both undertakings were very numerous, and caused what at that time appeared to be insurmountable difficulties. Work on the railroad had to be stopped time and time again from the fact of the laborers all dying off, and in the canal this difficulty has been given as the greatest cause of failure. It is probable, therefore, that the building of the isthmian canal, which has finally been undertaken by our country, is rather more a sanitary than an engineering problem. These two diseases, yellow fever and malaria, which were the great cause of mortality on the isthmus, are mosquito-borne, and mosquito-killing measures, similar to those which have been successful in combating both diseases in Havana, ought to accomplish much the same result on the isthmus; or at least to decrease these two diseases to such an extent that the work can be carried to a successful issue.

The facts which the report assumes as established with regard to the *Plymouth* are these: That the U. S. S. *Plymouth*, on October 6, 1878, sailed from Portsmouth, N. H.; on the 19th she arrived at Christianstadt; on the 21st she proceeded to St. Thomas, where she coaled. On the 25th she proceeded to Frederickstadt, Santa Cruz, where she remained until the 7th of November. On the evening of the 4th of November a case of yellow fever developed. Between that and the 7th, seven cases of yellow fever occurred. No case occurred after November 7.

The ship at once proceeded north, reaching Norfolk, Va., November 18, and Portsmouth, N. H., on December 1. From January 8 to February 12 the vessel was empty and thoroughly exposed to the cold of Boston harbor. On February 12 the crew returned, and on March 15 she sailed from Boston for a cruise in the West Indies. On the 19th and 21st of March two cases of yellow fever developed aboard.

The question in this case is to account for the yellow fever under the mosquito theory, and the particular point to be accounted for under this theory is the redevelopment of yellow fever on March 19—the last possible date of infection being November 10—considering the exceedingly unfavorable condition in which the ship had been placed during this time for the life of the mosquito. I say the 10th, though the last case occurred on the night of the 7th, since the mosquito might have been infected, as far as our experience goes, at any time within the first thirty-six hours of the disease in the patient.

If I accepted the facts as recorded above, my explanation would be as follows: That the ship had in all probability, gotten a supply of stegomyia mosquitos in her former cruising in the tropics. She left the tropics in June, 1878, and the weather between June and the first of November, at Portsmouth, N. H., had not been cold enough to kill the stegomyia. That on reaching Christianstadt, on October 19, somebody went ashore and contracted yellow fever. The case was so mild that it escaped observation. About the 21st this patient was taken sick, and on the 21st this case infected several of the stegomyia mosquitos aboard. About November 2 these mosquitos became capable of conveying fever, and on November 4 the first case came down with fever. It is possible, of course, that the ship became infected by having infected mosquitos blown aboard while lying at the dock at St. Thomas taking on coal. But I think this is unlikely. If infected mosquitos had gotten aboard, it would probably have been one or two, and we would have had a single case occurring about the 25th or 26th of October, and a secondary case occurring about the 8th or 9th of November, at the earliest. The ship arrived at Santa Cruz on the 25th.

There were evidently quite a number of infected mosquitos on board, and it seems to me much more probable that the mosquitos became infected from the introduction of a sick man. My own experience points toward the disease spreading by means of a sick man, rather than by means of infected mosquitos passing from house to house. A female mosquito would hardly have bitten a second time within three days, and as eight cases occurred inside of four days, there must have been at least eight infected mosquitos aboard, and in all probability a good many more. The disinfection which took place on the 8th killed most of the infected mosquitos, and the getting into a cooler climate at this time of the year rendered torpid those that had escaped.

All who have had practical experience in yellow fever are quite aware how possible it is that a man may have a very mild attack of yellow fever and not take to bed, and some of the experimental cases that I have seen in Havana would probably not have reported to the doctor if they had been sick aboard ship, particularly if the patient had been an officer who had no hard manual labor to do, and could lie up and take care of himself for a day or two. But this point is not very important in the explanation of this case. I am explaining what I think is the most probable way of the introduction having occurred. As the ship lay at the dock and coaled, it is possible that the infected mosquitos blew aboard there. I put the date of my hypothetical case getting sick as the 21st, supposing him to have been bitten by an infected mosquito at Christianstadt on the 19th, and giving him a period of forty-eight hours for incubation.

The report states that there had been one case of yellow fever in the island of Santa Cruz about three weeks before, which had been fatal. While the crew were not allowed to go ashore at either port, except at Santa Cruz for drill, the officers and stewards were allowed to go between the hours of 10 A. M. and 5 P. M.

Allowing, I repeat, this case forty-eight hours for incubation, the man would have been taken sick on the morning of the 21st. Experimentally we had quite a number of cases which incubated under forty-eight hours. On the 21st he was bitten by the mosquitos on board, within twenty-four hours after he was taken sick; this has been done experimentally. allowing twelve days for the incubation in the mosquito, would bring it up to November 2, and forty-eight hours for incubation in the man, would bring it up to November 4, when the first case occurred on board the *Plymouth*.

It might be that the mild case came aboard at St. Thomas, on the first day the ship came in, the 21st, just as I suggested that it came aboard at Christianstadt. But as this would shorten the time by two days, I think the probability is in favor of Christianstadt. But taking the minimum periods, as observed in the experimental cases, it could be very well explained as coming aboard at St. Thomas.

Now comes the difficult part of the explanation, under the mosquito theory. The latest date at which a mosquito aboard the *Plymouth* could have become infected was on November 10. Experimentally, they have not been able to be infected after the third day of the disease in man. I have, therefore, to explain the life of the stegomyia from November 10, 1878, to March 17, 1879, a period of 127 days. The report states (page 10) that during October, November, and December, 1878, there occurred on the *Plymouth* seven cases of yellow fever, three cases of continued fever, and one of intermittent fever. Page 14 of the report states that from the time of leaving Portsmouth to November 4 there had been no case of fever of any kind aboard. So that the three cases of continued fever and one of intermittent fever must have occurred between November 4 and December 31. If either or all of them were cases of mild yellow fever, the time to be accounted for would be shortened by as much as the date of occurrence fell after November 7. I assume the date to have been March 17, as the first patient took sick on March 19, and he might have been bitten by the infected mosquito on March 17, though the longest case of incubation in man in the experiments by the Army Board was a little over six days. Still, as the ship was in Boston six days before the case occurred, it is more probable that the hibernating mosquitos did not stir around until the ship had gotten to a warmer latitude, say the 16th or 17th. It is, however, entirely possible for a hibernating stegomyia to be warmed up in a closed room and become active, even with a pretty cold outside temperature. As the ship was occupied by the crew, although in a very cold climate, there would be no difficulty in accounting for the few mosquitos hibernating in protected places up to January 8. From January 8 to February 12 everything was taken out of the ship, and all parts were exposed to cold much below the freezing point, and a thorough and careful disinfection was made. But evidently there were many parts of the ship, under the floors and in the protected parts, where the temperature was not reduced to a very low point, and to which the disinfectants used did not penetrate. The Board which examined the ship in February, 1880, after a second thorough freezing, states on page 22:

> "Under the lead lining the sheathing was entirely rotten and blackened as if the wood had been charred, and in this rotten wood dead rats and their nests were found. The thick strakes and ceiling were badly decayed. On cutting the bread-room floors, confined air of offensive odor escaped. A second floor had been here laid above the original floor, and between the two was a confined space about three inches deep, from which living and active flies crawled out. It is plain that, although ice had long been standing in the fire-room, this space had not been sufficiently chilled to kill the flies."

From this quotation it can be seen that where it was possible for flies to remain active and lively, it would also be possible for a mosquito to hibernate, and that into such places around a ship to which rats and flies had access it was entirely possible for a mosquito to enter and live, so far as cold and disinfectants were concerned.

And again on the same page:

> "These spaces, as is shown by the presence of living flies, are so protected from external atmospheric changes as to be practically unaffected by either heat or cold, and have probably not been reached by any of the disinfecting agents heretofore employed."

These quotations, I think, demonstrate the possibility of the mosquito living from January 8 to February 12, in spite of the severe cold and disinfection to which the ship was exposed during this period.

On the 19th of March, or possibly a few days earlier, the ship became sufficiently warm for the hibernating mosquitos to revive. Only two female infected mosquitos had survived the rigorous measures taken. These bit the two seamen and gave them yellow fever. The two infected mosquitos were either killed accidentally or again hibernated when the ship turned north, and died from natural causes. I say two mosquitos, as it was necessary to have at least that number to give two different men yellow fever within forty-eight hours. A mosquito after once filling with blood does not bite again within about three days. And it is probable that a very small number of mosquitos survived the ordeal through which the ship was put.

The report does not say at what latitude yellow fever appeared for the second time, but as it was four days out from Boston, it was evidently pretty well down toward the Windward Islands. One hundred and twenty-seven days is a very long life for a mosquito, as far as my experience goes. How they survive in the frigid zone is not known, but as the mosquitos native to those latitudes occur in very much greater numbers than they do in the tropics, if they survive at all in the adult form, they must hibernate for at least six or eight months. I have known a stegomyia mosquito to live sixty-five days between the biting of the first and last case, and this particular mosquito finally died from a traumatism. We had another mosquito at Las Animas Hospital, hatched in captivity and kept in a jar all its life, that lived one hundred days. These examples do not, of course, quite cover the case in point, but if a mosquito born and bred in captivity could live a hundred days, it would be no great stretch to believe that one in the more favorable circumstances of the hold of a ship might live one hundred and twenty-seven days.

I submit this as a reasonable explanation, under the theory that the infected stegomyia mosquito is the only means of transmitting yellow fever from man to man, of the occurrence of the second outbreak of yellow fever on March 21, 1879, on board the *Plymouth*.

Personally, however, I should be rather inclined to question the diagnosis of the two cases occurring in March, 1879. It would be very unusual for the stegomyia, as we know her here, to escape the cold and disinfection, as described with regard to the *Plymouth*. While I think there is a possibility of her doing so in such parts of the ship as the fly could survive in, it would be unusual, and the more probable explanation, from the record of the case as given in the report, is that the two cases referred to were not yellow fever. In the history of yellow fever it is very unusual that the infection could have survived such a course as the *Plymouth* was put through. I am speaking now purely of the history of yellow fever, whether we believe it to have been conveyed by fomites or by a mosquito. This case of the *Plymouth* is probably the most extreme case recorded, and the two cases on which the diagnosis rests should be proved beyond any question or reasonable doubt.

The first case, that of Richard Saunders, had a very fair history of yellow fever, and if it had occurred in Havana, with yellow fever about, I would accept the history as it is. But under the exceptional circumstances, the record is an exceedingly imperfect one on which to base a diagnosis. The temperature is given on the evening of the first day, on the morning of the second, and on the evening of the second; on the third and fourth days no record is given. On the fifth day, the 25th, it is stated that the temperature is 102° throughout the day; on the sixth day, the 26th the temperature is again given, and from this time, it is stated, the temperature subsided. The other symptoms as reported bear out the diagnosis of yellow fever, but the temperature, as given, would indicate a very sharp case of yellow fever. I would have expected in such a case the jaundice to have been pronounced, and to have continued for more than a week. There is no mention made of the condition of the gums; not only should they have been very markedly puffy, but there should have been very extensive hemorrhage. As no reference is made to this striking symptom, it apparently did not occur. The broad and tooth indented tongue, as described, would be against yellow fever, though it appears sufficiently often not to be a very pronounced diagnostic point.

In the second case, that of Eagan, the temperature is mentioned only once, and it is stated that the man died in a typhoid condition on the eleventh day of the disease. It is stated that the symptoms and appearance were the same as those of Saunders. He probably had albumin in the urine, as Saunders had, though it is not specifically stated. The irritability of the stomach is described as being great. This the former case did not have. He fell into a typhoid condition and died on the eleventh day. This is a very unusual mode of death in yellow fever. No uræmia or convulsions are spoken of, nor is hemorrhage referred to. In the case of Eagan, in which death occurred, there should surely have been hemorrhage from the gums, and, as the stomach was very irritable, gastric hemorrhage, to some extent, also. No autopsy was made, and no description of the body given, as to whether or not jaundice occurred after death. This is so marked in yellow fever that one would expect it to be noted.

This would be my criticism upon the report in the two cases, Saunders and Eagan. The symptoms are not sufficiently recorded to make a diagnosis of yellow fever. I think in the second case, Eagan's, the symptoms as recorded rather tend to a diagnosis of not yellow fever. The report states, page 13, that in November, 1878, Surgeon T. Woolverton was the medical officer in charge. It does not specify who was the medical officer making the diagnosis in March, 1879. It would strengthen the case if the same officer made the diagnosis on both occasions. It would help the diagnosis if it were known whether or not others were sick on board about this time of any other disease. The report, page 11, states that in January, February, and March, 1879, two cases of yellow fever, one of continued fever and one of intermittent fever occurred on board the *Plymouth*; whether or not they occurred about the same date as the yellow fever, the report does not specify. As recorded, I think continued fever would be a fairer diagnosis than yellow fever for these two cases.

What the disease was in these two cases, I do not think can be definitely determined from the symptoms recorded. Surgeon-General Rixey of the Navy has written me that the report contains all the data concerning these two cases, in the possession of the department, But that it was yellow fever should be shown beyond a reasonable doubt before an explanation of the infection of the ship is demanded.

The following letters from two acknowledged authorities on the subject of yellow fever and of mosquito infection were written in answer to my request for an expression of their views:

AUGUST 4, 1902.

Major W. C. Gorgas, Surgeon, U. S. Army:

MY DEAR MAJOR GORGAS: In compliance with your request, I shall briefly state my views with regard to the doubts entertained by my respected friend Dr. Stanford Chaillé as to the possibility of explaining the two belated cases of yellow fever on the *Plymouth*, in 1879, through the exclusive agency of contaminated mosquitos, in accordance with my original mosquito theory. I still hold the same opinion which I expressed in my first paper on the subject, twenty-one years ago; namely, "that in the notorious instance of the *Plymouth* the two cases which occurred at sea, after the vessel had been disinfected and frozen during the winter and after four months had elapsed since the last of the previous cases had been recorded on board (the preceding November), can be readily accounted for by the hibernation of mosquitos which had bitten the former yellow-fever patients, and which, upon finding themselves once more within tropical temperatures, recovered from their lethargy and bit two of the new men of the crew." (See p. 18 in the English translation of my original paper on the subject, published in the *Revista de la Associacion Medico-Farmacéutica*, for January, 1902, of which I am sending you a reprint). Since that time, notwithstanding the important contributions which have been made to the study of the etiology of the disease, I have found myself at a loss to find any other theory by which the above-mentioned facts might be explained.

The theory of miasma in connection with yellow fever has long since been exploded, the theory of a germ which requires to go through certain transformations among the inanimate surroundings of a previous case leaves unanswered the question as to the reason why the germ after having reached its maturity, should have acted upon two of the non-immunes, leaving all the others untouched. It might be argued that, since the yellow-fever mosquito is capable of transmitting the disease, flies of the kind which were seen to creep out of the crevices in the rotten wood when the vessel was subsequently re-inspected might do the same, as also fleas, bedbugs, and other blood-sucking insects. But there is this difference: that the Stegomyia species of mosquito only dwells in yellow-fever countries, or in places where, during the summer months, the disease may be propagated, while the flies, fleas and bedbugs, which have been supposed to share with the Culex mosquito the faculty of transmitting yellow fever in Havana or Vera Cruz, are not different, so far as I know, from the insects of that kind found in the city of Mexico, or in Puebla, in neither of which places is the disease ever transmitted from the sick to the healthy.

Regarding the diagnosis of the two cases on board [of the *Plymouth*, I see no reason for doubting its correctness. The clinical history, temperatures, pulse, and general course of the first case (Saunders) appears to me to be quite typical of the disease; about the other case (Eagan), the account is very incomplete, it is true, but, so far as it goes, it is quite consistent with the diagnosis, the death having occurred, not on the eleventh day, but, according to the report, on the ninth, which is a frequent occurrence in yellow fever.

I do not think it necessary to bring forward any additional arguments to bear upon the question at issue, but it would be a very great satisfaction to me if I could contribute to bring over to our own views a man whose keen judgment I have had occasion to appreciate. Indeed, it would only be a small return for the great service which at one time he rendered me; for it was through his close reasoning and unanswerable facts, as set down in his preliminary report of 1880 (which he kindly sent me), that I became convinced of my former errors, and set to work in a new direction, which soon led me to the discovery of the yellow-fever mosquito.

Yours very truly,
(Signed) Charles J. Finlay.

August 11, 1902.

Major W. C. Gorgas, U. S. A.:

My Dear Dr. Gorgas. I have to thank you for the opportunity to read once more the report on the outbreak of yellow fever on board the U. S. S. *Plymouth*, and, as you request, I shall give you my views concerning the said outbreak:

It appears to me that it is difficult to explain no matter which of the theories of the etiology of the disease we may maintain. At the time of the occurrence we all looked upon it as an exceptional case, and as such it stands today, though we are much richer in the possession of actual facts concerning the etiology of yellow fever.

Under these circumstances one is justified in demanding that a more thorough clinical study of the cases of Saunders and Eagan be presented before we accept the diagnosis of yellow fever. The case of Eagan can certainly be dismissed as proving nothing, in so far as we can judge from the clinical history. In the case of Saunders there is no statement as to the amount of albumin found in the urine. We are not informed of the duration of the disease. We are surprised to find that, though the case was a severe one, the pulse is not recorded as beating slower than 80 at any time, and jaundice is mentioned as a symptom only during the convalescence.

But if those who adhere to the theory of fomites are willing to take such records as evidence of yellow fever, we, who accept fully the doctrine of mosquito infection, see nothing absolutely incompatible with our doctrine in the facts of the case. Those who are bringing it up as proof against the mosquito being the only means of conveyance of the disease, are obliged to suppose that some sort of fomites escaped the action of cold and the disinfectants, and they have pointed out how living organisms, and even flies, escaped after treatment of the ship by the the same agencies during the following winter. We have only to follow the same line of argument to explain this exceptional case on the doctrine of mosquito infection; and we can bring in our support the known facts concerning the long duration of life and the hibernation of mosquitos. We can suppose, as others do concerning their fomites, that infected [illegible], through imperfect attempts at freezing and fumigation.

Basing our calculations on the reported cases of yellow fever mentioned in the history of the ship, I should fix the necessary duration of life of the two insects that infected Saunders and Eagan at 126 days. Now I have had in my jars a mosquito that was capable of biting on the 105th day of its life, and it perished on that day by accident.

But it is possible that the duration of life of the mosquitos that bit Saunders and Eagan may have been shorter than 120 days. The last cases reported of the previous outbreak occurred on the 7th of November, 1878. Mosquitos became infected from them on the 10th and possibly the 11th. These would give us the period mentioned of 126 days. But the mosquitos infected at St. Thomas or at Frederickstadt, or on board the vessel itself—the mosquitos, I mean, that produced the cases on the 7th of November—may have produced at any time during November, some mild, unrecognized case of the disease. Though the ship sailed to Norfolk, Va., during that month I notice that the average temperature on board for the month was 65.8 on the spar-deck and 72.5 on the berth-deck. The temperature for March, when the second outbreak occurred, was 49.5 and 62, respectively. See table opposite page 47 of the report. A mosquito bred on board the ship during the month of November—say, on the 23d, the day she left Norfolk—or a young mosquito taken on board at Norfolk, could have bitten the mild, unrecognized case. Such mosquito would have been about 114 days old on the 15th of March, when Saunders and Eagan were infected. Accepting the possibility of such mild, unrecognized case, it is possible to reduce the number of days of the duration of life of the mosquito in question even to 106.

For many years I have insisted on the importance of the mild, unrecognized cases of yellow fever as factors in the maintenance and propagation of the infection. During the epidemic of Jacksonville, in 1888, we had a detention camp at Camp Perry, on the St. Mary river. We were successfully allowing a large population to pass through our camp, and to go north. We considered it as a test of our measures that the towns immediately to the north of us, Folkstown and Uptonville, were receiving our discharged population without becoming contaminated. One day I saw Mr. Upton, the owner of the lumber mill at Uptonville, sitting in this station waiting for the train. His appearance made me suspect that he was convalescing from yellow fever. I felt so sure of my diagnosis that I insisted upon his going into observation at Camp Perry. I remember well the doubts that were entertained as to the possibility of such being a case of yellow fever. Three days later the housekeeper of Mr. Upton and her husband were down with yellow fever. Mr. Upton had passed most of his attack in his buggy, moving about the country. He had rested two or three nights in Uptonville, and the two persons mentioned had waited on him, and slept in his house. To complete the history I should mention that Mr. Upton had contracted the disease by running through the lines into Jacksonville. Of course, neither he nor his attendants had the remotest suspicion that the case had been one of yellow fever.

Yours very truly,
(Signed) John Guitéras.

SOME CLINICAL AND OPERATIVE PHASES OF APPENDICITIS.

By A. H. CORDIER, M.D.,
KANSAS CITY, MO.

PROFESSOR OF ABDOMINAL SURGERY IN THE UNIVERSITY MEDICAL COLLEGE; EX-PRESIDENT MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

In the early history of the clinical phases of appendicitis the discussions were mostly along the line of diagnosis. The question of typhlitis, perityphlitis, and other supposed pathological changes in the ileocæcal region was discussed at length by the greatest medical minds of that day. Later the fallacies of those who maintained that the symptoms now recognized as those of appendicitis were due to a perityphlitis, etc., were dropped, and the true condition was recognized and accepted by most surgeons and physicians. Then a new discrepancy developed in the minds of the profession—that is, how shall these cases be treated? Along this line there have been written more essays, and longer discussions have been held, and more varied opinions expressed, than on any other problem ever before the profession for proper solution. That those entering into these varied discussions have been sincere and honest no one will deny. That there exists a want of unanimity is only too true. The lay papers, ever ready to enter into scientific disputes, have not made this disagreement an exception, and the vast amount of harm done and the number of lives lost as a result of this source of information to the lay readers would be hard to estimate.

The diagnosis of appendicitis offers to the experienced physician very little difficulty. As a rule, the determining of the exact location of the pathology in the appendix and the extent of that change is not so easy; however, in many cases the experienced surgeon can tell quite accurately the character and extent of some of those changes before the operation. This uncertainty in foretelling the condition the appendix is in and how the case will terminate has led to the most bitter discussions entered into on this subject. It has led to one class of surgeons taking a position of waiting until what they call definite prognostic symptoms develop; while another class maintain that to delay is dangerous, as the so-called characteristic symptoms may not appear at all or be delayed until the safe period for operating has passed. A third class of surgeons say wait in all cases and operate in the interval of the attack. And yet others are found who oppose operations in every case, and continue signing death certificates, "Peritonitis," "Inflammation of the bowels," "Obstruction of intestines," etc.

All kinds of medical management have been advised, from opium narcosis to total abstinence of all food and liquids by the stomach. With all this array of professional opinions, can we wonder much at the articles appearing in the lay press? Why should this diversity of opinion exist in this day when opportunities are so frequently presented to all to gain a similar knowledge on this subject?

Basing the operative indications upon a purely conjectural (in many cases), or a pathological classification will often lead to error in staying the surgeon's efforts at relief. To say that this case is one of appendicitis gangrenosa, or that it is one of so-called catarrhal variety, and deciding for or against the operation, will lead to serious mistakes in many cases. I do not wish to create the impression in this paper that an operation is imperative in every case of acute appendicitis—far from it. I do believe that 60 per cent. of all cases of acute appendicitis recover from the primary attack, thus leaving 40 per cent. in the uncured and doubtful class to run the gauntlet of recurrences and the dangers incident thereto. My position with reference to the time when to operate is that if every case of appendicitis was operated on as soon as the diagnosis was made, the mortality would be reduced to practically nothing. Dr. Lloyd of New York kept track of twenty cases of this disease that have been observed for a number of years. Twenty-four per cent. died. 70 per cent. had recurrent attacks. Fitz's figures are about the same as Lloyd's. The medical man and the waiting surgeon should keep their cases under observation a much longer time before reporting them cured without an operation. Many a case of appendicitis is reported by three or a dozen physicians as having been cured by medicines, the same case having been operated on by some surgeon later, who reports the case anew. Many cases of acute appendicitis never have an *interval* if a delay in operating is permitted. In many cases the pathology in a first attack of appendicitis is of such a character as to leave no doubt that the patient had been having unhealthy changes in the appendix for weeks or months. A fecal or other concretion may have remained in the appendix for months, slowly but surely destroying the surface epithelium, thus breaking down nature's protective barrier to septic microorganism invasion to the deeper structures.

In a primary attack of three hours' duration, as far as clinical history is concerned, an ulcer through the mucous and muscular coats, or even a complete perforation may be met with, the patient giving no history of a previous acute attack, or even of any obscure or remote symptoms of these changes taking place in the appendix. I have operated on large, healthy young men within six hours after the development of the first acute symptom and found a perforated appendix, or a complete stricture at the base of the appendix from old inflammatory changes at that point, the appendix being much dilated and filled with virulent pus.

The clinical history in this disease is often misleading. Take for instance the fever; in one case the patient may have a temperature of 104° F. on the first or second day and a pulse rate of 96, or even 84. An operation reveals a small ulcer in the appendix as the only pathological change present. A temperature of this height in another case with primary history the same on the second or third day, may go down to normal and many of the symptoms improve; at operation an appendix is found perforated, with a few ounces of pus surrounding it, or the appendix may be completely gangrenous, with not an adhesion about it. We are told that a high temperature implies, as a rule, streptococcal infection, while a low temperature points to the colon bacillus or staphylococcus as the cause of the mischief. An operation reveals a general diffused septic peritonitis with fluid teeming with the streptococcus, yet the patient never had a temperature above 101° F. So this symptom as an operative indicator loses much of its value in the face of demonstrated facts at the post-mortem or on the operating table. The operator who relies upon the height of the temperature as a guide to the kind of infection or to tell him when to operate, will make many costly mistakes. Temperature increase is of value in making a diagnosis of appendicitis, but is unreliable when used beyond this in the question of prognosis and proper treatment of these cases.

The pulse rate is, as a rule, increased in frequency, and more reliance can be placed on it in matters of prognosis than on the temperature. This is true especially in the later stages of a general peritonitis, but as long as the disease is confined to the appendix proper, or to the immediate vicinity of the appendix, its behavior is very erratic and misleading. An appendix filled with pus may raise the pulse only ten beats, while a well-walled-off appendicular abscess may be accompanied by a pulse of only 70. A rapidly-spreading peritonitis is usually associated with a rapid increase of the pulse, while there may not be any peritonitis at all the patient may have a pulse rate of 140 from the rapid absorption of ptomains and septic microorganisms and their prolific increase in the blood. This is a clinical feature often lost sight of by the practitioner. The rapidly constitutional septic cases are the most fatal types of this disease. The removal of a diseased appendix and drainage of iliac fossa will not remove streptococci in the blood circulating through the brain, liver, and other structures of the body.

Pain as a symptom of this disease is always present at some stage, yet its character and intensity is as variable as any one symptom of the disease. In many cases, to rely upon the severity of the pain to predict the outcome of the case would be disastrous. In the beginning the pain may be referred to a point above the umbilicus, with waves of colic over the abdomen. These pains are often quite severe, and the appendix may remain in a comparatively good condition; yet the most virulent pus may be escaping from a perforated appendix into the general peritoneal cavity, and the patient may tell you he is much easier than on the first day of the attack.

The most unfortunate discovery ever made in appendical explorations was that of "McBurney's point." I do not refer to this in a disrespectful manner, because I fully appreciate the great work of this skilled surgeon. Dr. McBurney is not responsible for the want of a proper interpretation of the various locations of the appendix. Many fail to realize that the appendix "points" according to its location, to its length and to the location of the pathology in the organ. This is another clinical feature, to rely upon which, in treatment, may lead to error. Pain on pressure or tenderness is to be distinguished from symptomatic pain mentioned by the patient. A patient may complain of much pain at many points in the abdomen, yet pressure pain (tenderness) will be found in only one location, and that point will be nearest to the site of that portion of the appendix diseased. I consider this one of the most trustworthy indications of the true condition existing in and about the appendix. The palpating, skilled fingers I believe can collect more reliable evidence for or against operation than all other methods or histories combined.

Intestinal gaseous distention, as a symptom of danger, is valuable when present, but its absence is often misleading, as some of the most rapidly fatal cases I have ever seen have not been distended at all. I consider the quick formation of gas in these cases (when morphine has not been given), one of the most dangerous symptoms, and especially is this true if the pulse rate is greatly accelerated and the pain diminished—all symptoms pointing to a rapid and general extension of the peritonitis. To delay here means, with rare exceptions, a rapidly fatal termination. Persistent vomiting is a bad indication, and is usually accompanied by the symptoms just mentioned.

In a general summary of these cases the operative indications for immediate interference are often present and well marked, and need not mislead anyone of much practical experience, but with this class all are familiar. The object of this paper is to lay stress upon the fact that to expect to find these typical symptoms, and be governed by their presence or absence, is a mistake, and will cause delays and fatal errors in cases that should be operated on early and saved.

The presence or absence of a leucocytosis in cases of appendicitis, to decide the question to operate or wait, is so uncertain and misleading as to not be taken seriously in these cases.

In skilled and aseptic hands, no uncomplicated case of appendicitis should end fatally from the operation if too much delay is not permitted before operating. When a case proves fatal in such hands it is not the operation that kills, but the patient dies in spite of the operation. An incision through the abdominal walls, with removal of the appendix, is not going to head off the peritonitis under the liver and left kidney. No case of appendicitis should be permitted to go on until the pancreas and spleen are bathed in pus. All timely operations are easy, free from adhesions, with no open wound with tuberculous or other drainage and no subsequent hernia. A little incision, quick surgery, and a closed wound are symbolic of a moist tongue, a slow, soft pulse, a flat abdomen, a cheerful, quick, and comfortable convalescence, with no post-operative complications. What more could the surgeon wish or the patient desire? Delayed operations mean a game of chance, in which a human life is the stake; if the medical attendant loses, it means a death; if he wins, it means a tardy recovery, a long incision, with painful dressings to the patient, and bad odor in that part of the hospital from fecal fistulæ and offensive pus, and post-operative hernia occasionally.

With these truths before us, our duty is plain, and we should meet these obligations intelligently

TRAUMATIC INJURIES OF THE LIVER.*

By J. L. WIGGINS, M.D.,
EAST ST. LOUIS, ILL.

The number of reported cases of lacerations of the liver has increased of late years, as the field of abdominal surgery has been enlarged.

The diagnosis of this lesion, divested of direct history of injury, does not differ materially from injury to any of the abdominal viscera, being dependent on the presence of shock and hemorrhage. This is of slight importance in locating the lesion, as hemorrhage follows laceration of any of the contained organs, and shock, which indicates merely the abolition of the controlling influences exercised by the nervous system over the vital organic functions of the body, may be produced with equal severity, by mental as well as physical conditions

In examining reported cases one is impressed with the number in which it is further noted, that vomiting of greenish bile ensued, this being frequently tinged with blood, yet no logical explanation is advanced as to the reason why blood should be in evidence in the vomit of those suffering from hepatic injuries, except the suggestion that possibly there was an injury to the stomach which had escaped observation. In the case to be reported, not only can we exclude the stomach from any injury, but also every other organ in the abdomen, as all were closely examined previous to the location of the wound. We may well give some attention to this clinical symptom as an aid in locating more definitely obscure lesions, especially in non-penetrating wounds of the abdomen.

Usually the anterior surface of the liver is involved, this on account of its exposed position, and of the fact that in many instances a fracture of the ribs, the result of the violence, precedes injury to the liver. Whenever the sharp point of a fractured rib penetrates the liver substance, shock and hemorrhage follows immediately. Under these conditions blood escapes without restraint into the free abdominal cavity. If, however, there is no wound of this nature, the clinical symptoms will be masked, and the patient need not present marked symptoms of shock, although indications of abdominal injury may exist, from a period ranging from a few hours to several days, we may then have a sudden collapse, or the formation of abscess in the hepatic substance. This has been the observation without any clear explanation.

I would call attention to a few anatomical points for a clear understanding as to how delayed shock, abscesses, bloody vomit or stool, may ensue. The surface of the liver is covered by a strong fibrous capsule, which, under the name of Glisson's capsule, accompanies the portal vessels into the liver; all surface portions are further reinforced by a layer of peritoneum, except at ligamentous reflections the fissure of the gall-bladder, and the portal fissure. The liver substance is a soft solid, friable and composed of lobules, each of which represents an independent atom of the whole, the essential element being the secreting cell; the grooved surfaces of contiguous cells forming the beginning of bile-duct radicles, which pour their secretion into a common drain, which empties into the second portion of the duodenum, with the duct of the pancreas, about four inches from the pylorus.

---

*Read before the Illinois State Society.

The anterior liver surface being in contact with the thoracic cage, may, by impact, cause a separation of the friable tissue beneath, without causing a laceration of the serous or fibrous coats. Under these conditions we would have limited shock, referable to the sympathetic nerves, but blood and bile extravasation would be limited by the coverings and the further support of chondrocostal apposition. The fluid under these conditions would follow the law of projectiles, insinuating itself along the course of the least resistance. If adhesions following inflammatory action ensued, between the hepatic and diaphragmatic peritoneum, up to a certain point, the least resistance would be directed toward the center of the organ, the sides of the fissure being separated by the accumulation, to their utmost limit, then reversed along the point of adhesions, on outer surface until rupture ensued, followed by pouring of contents into abdomen. Before this takes place, however, we would find, according to the depth of the fissure, a greater or less quantity of blood, forced through the hepatic ducts into the duodenum, with a resulting bloody vomit, and if excessive, bloody stool.

The case presenting in my service was that of a Polander, aged thirty-one years, height five feet eight and one-half inches; weight 170 pounds; very muscular. Was seen by the assistant company physician, March 27, 1901, at 12.45 A.M. While manipulating the large shears at the Rolling Mill, he was struck in the abdomen by a piece of boiler iron. There was but slight shock; the patient was conscious and complained of severe pain in the left hypochondriac region. The following morning, pain was accentuated, tympanites ensued, and intestinal paresis developed. Temperature, 101°; pulse, 106, and of fair volume. Solution of magnesia sulphate was given, followed by high enema, resulting in a free bowel movement.

Second day.—A.M., temperature, 101°; pulse, 96. P.M., temperature, 100.4°; pulse, 88. At this time he was free from pain; bowels having moved four times during the day.

Third day.—A.M., temperature, 98.8°; pulse, 88. P.M., temperature, 98.8°; pulse, 70. Fluid nourishment was given without any bad results. The bowels were open. The symptoms at this time, as shown by temperature, pulse, and general condition, indicated no serious lesion. There was no marked pain at any point upon pressure, and the dullness over hepatic area extended but little below the normal line.

The case was considered past the point where it required any special attention. This condition continued until 10 A.M. of the fourth day, when, on rising, the patient was seized with sharp pain in the right side, followed by syncope and all indications of shock; temperature subnormal; pulse rapid. The nature of the injury at this time was not suspected. Vomiting of bloody bile ensued and also a large bloody stool. This condition suggested to my mind the bursting of a hæmatoma into the abdomen, which also connected directly with the intestinal canal; and the fact that the blood was freely mixed with the vomit suggested a point close to the pylorus.

The abdomen was opened by a free incision along the median line and was found to contain from six to eight liters of dark venous blood. An examination of the upper surface of the right lobe of the liver disclosed a stellate rupture two and one-half inches from the anterior margin, situated directly over the fissure of the gall-bladder, its diverging points being contained in the right lobe, while the spur was opposite the quadrate lobe. The wound was three inches long, the lacerated tissue being in close apposition. There was but slight hemorrhage, except at the point of convergence, where there existed a loss of hepatic substance about one-fourth by one-fourth inches.

The gall-bladder was greatly distended with about 4 ounces of dark greenish brown fluid, evidently of the same character as that within the free abdominal cavity. The wound was sutured with No. 2 catgut; abdomen cleansed and closed without drainage. At the time of, and following the operation, the patient was moribund. Intravenous injection of decinormal salt solution was given and repeated every twelve hours. His pulse ranged from 80 to 130, and his temperature from 98.6° to 103°. On the twelfth day after the operation, symptoms of shock again ensued with considerable pain in the hepatic region. He had much trouble with the bowels, they being loose, of waxy color, and mixed with blood clots. On the twenty-second day dulness was discovered over the liver, indicating reformation of the hæmatoma. I aspirated, withdrawing about three ounces of blood and bile.

On the following day I resected three inches of the seventh and eighth ribs, wiping out the cavity and introducing loose gauze drainage. His temperature, which was at this time 103°, fell to 100.6°. Two days later there was a free discharge of bile, saturating dressings and bed. The amount secreted daily being from two to three pints. The temperature ranged from 98° to 101°, and the secretion of bile gradually decreased until fistulous wound closed on July 17. A conservative estimate of the quantity of bile secreted in fifty-three days in which the wound was open is fourteen gallons.

The drain of biliary secretion caused great emaciation. All nourishment was rejected and nutriment enemas were expelled. The bowels did not move except as the result of high stimulating enemas.

The patient was discharged on August 10, 132 days from the time of the first operation. He resumed his work, and, so far as I am able to learn, has since suffered no inconvenience as the result of the injury.

Conclusions.—1. Delayed bloody vomit or stool, in obscure abdominal injuries, is indicative of rupture of hepatic substance without laceration of its fibrous or serous coverings.

2. No method of suturing can be entirely satisfactory. (*a*) Because if laceration is superficial it is not required. (*b*) If laceration is deep, the dead space cannot be obliterated; as a consequence there is an accumulation of arterial and venous blood mixed with bile from this vascular organ, which may become infected, forming an abscess; or if accumulation is excessive, break line of suture and tear protective adhesions.

3. The suture material, to be of any service, must be large; to control hemorrhage it must exert pressure. In the first instance many lobules must be destroyed, and there will be interference with venous and arterial branches and secreting radicles. In the second, a tight-drawn suture may cut through friable structure or cause tissue necrosis.

4. The use of any sealing material, with the possible exception of the actual cautery, is not sound in theory or warranted by results. The best results accrue from drainage by the most direct route and isolating damaged structure.

5. Immediate operation, irrespective of degree of shock, is the only rational method of treatment and the only one which has yielded good results.

New York, October 4, 1902.

THE TREATMENT OF TYPHOID-CONTAMINATED SEWAGE.

In every country of the world, but more especially, perhaps, in the United States, the question of extirpating typhoid fever is one of the first moment. Many cities of this continent are peculiarly subject to epidemics of the disease, and Chicago at the present time is suffering from a somewhat virulent outbreak. The cause of these periodical visitations is, of course, not far to seek. Undoubtedly a contaminated water supply and general defective sanitation is chiefly responsible for such oft-recurring epidemics of enteric fever. This being the case, any effective means of ridding sewage of typhoid germs, without exaggeration, would be regarded as an almost incomparable boon conferred upon humanity.

The fact is freely admitted that in Europe, and in Great Britain in particular, greater progress has been made toward the solution of the sanitation problem than in America. There are here notable outstanding exceptions, but, as a rule, sanitary efforts have been more intelligently carried out, and sanitation is, on the whole, further advanced in the cities of Germany and of Great Britain than in those on this side of the ocean. The matter, which now for some few years has occupied the supreme attention of scientific sanitarians, is how to render sewage free from the germs of typhoid. Bacteriologists enthusiastically grappled with the subject, and the outcome was the septic tank.

A short time ago, the annual Congress of the British Royal Institute of Public Health was held at Exeter, the city which may almost be termed the home of the septic tank. Dr. Ranson Pickard, who is in charge of the bacteriological experimental department of the Exeter Sewage Works, read a paper before the Congress, in which he said that "however disagreeable sewage might be to the senses, its power of reproducing disease was far more important, and it was easy to conceive that a system of sewage purification might be very good in getting rid of those parts of the sewage which were offensive, and yet it might not interfere at all with the disease organisms contained in the sewage. He had experimented in three directions in order to determine: (1) The action of sewage sterilized by heat upon typhoid germs grown upon gelatin; (2) The action of crude sewage upon typhoid germs; (3) The action of intermittent filtration upon typhoid germs previously exposed to crude sewage for forty hours in warm weather."

The sum of the deductions which Dr Pickard drew, as a result of his experiments, was that the septic tank system, destroyed a distinct proportion of the typhoid bacilli which might be present in the sewage. Some were killed in the tank, and others probably had their vitality diminished, so that exposure in the filtering beds much more easily killed them than if the sewage was passed directly on to the filters. It was not possible to state with any exactness the proportion destroyed under all variations in the duration of stay in the tank and filters, dilution of sewage, alteration of temperature, etc. There were several fallacies which must be remembered in making exact deductions as to the tank and filters. The main one was that the number of typhoid germs introduced in the experiments vastly exceeded any possible contamination by the excreta of typhoid patients.

The second report of the British Royal Commission to consider methods of treatment and disposal of sewage has been recently published. Some of the most important papers therein contained were contributed by Dr. Houston, dealing with the subject viewed from a bacteriological standpoint. It would appear, from a brief consideration of these papers, that the treatment of sewage in bacteria beds although much progress has been exhibited in bringing the method to a degree of effectiveness—is at present far from being an ideal plan of rendering sewage innoxious as a disseminator of typhoid fever. Nevertheless, the prediction may be made with a reasonable amount of certainty, that the method of disposing of sewage by bacteriological treatment will advance in public favor. At any rate, under the existing septic-tank system—which is, as it were, in its infancy—many of the pathogenic germs are killed, and the vitality of more is distinctly diminished.

TREATMENT OF INOPERABLE CANCER.

In the Section on Surgery at the meeting of the British Medical Association, a discussion took place on the above subject. Mr. Henry Morris of London, a recognized authority on the matter, read the first paper.

Mr. Morris first defined what he meant by "cancer" and the term "inoperable." There were, he said, for practical purposes, four groups of inoperable cases: (1) Primary cancer, affecting inaccessible parts or vital organs; (2) Primary cancer which, although at first removable, had advanced beyond the limits within which a local operation was prudent and complete removal possible; (3) Certain cases of acute diffuse carcinoma and very rapidly growing or widely infiltrating new growths of exceptionally virulent character, and (4) Recurrent carcinoma in which the disease had recurred in many places, or in parts where it was impossible to reach it.

As to the various modes of treatment, remedial and radical, Mr. Morris arrived at the following conclusions:

1. That the serum treatment of malignant disease is not of the slightest use in carcinoma; that not one-half of the cases of spindle-celled sarcoma disappear under treatment with Coley's fluid; that the treatment by Coley's fluid has many dangers, and

should never be employed except in absolutely inoperable cases.

2. That Beatson's treatment is limited in its action to cases of mammary carcinoma, and the local and glandular recurrences after mammary carcinoma, and that even of these cases only a small proportion are influenced by the treatment, whilst neither as a cure nor a palliative can it be relied upon in any given case.

3. That rodent ulcer has in the Finsen light and in the *x*-rays its most successful treatment, so far as we know at present; and that this is true not only of cases otherwise inoperable, but also of operable cases, because of the excellent cosmetic results and of the effect upon insidious and non-evident foci. There are, nevertheless, cases of rodent ulcer which resist the light and the *x*-ray treatment, and some of these cases are successfully treated by excision and caustics.

4. That sarcoma, epithelioma, and the other forms of carcinoma are best treated, whenever possible, by early excision, and that all forms of treatment hitherto tried in inoperable cancers of these kinds are uncertain and inconstant in their effects, and untrustworthy as to the durability of the results they produce. In the vast majority of cases they are quite without palliative influence of any kind, except possibly in relieving pain.

5. That the boundary line between what are considered operable and inoperable cases needs revision from time to time; that the tendency to extend the limits of operable cases needs, in some instances, to be restricted, and in others possibly there may prove room for fuller extension.

6. That it is open to question whether some of the operations performed for relief or prolongation of life in inoperable cases of malignant disease should not be abandoned, and whether in other cases palliative operation ought not to be more often performed.

7. That investigations into both the cause and nature of cancer are of the first importance, as being more likely to lead ultimately to the cure than excision.

8. That, with few exceptions, the attempts to cure cancer by means other than early and free operations have been hitherto almost invariably futile.

9. The complete ignorance as to the cause, nature, and curative treatment of cancer has long pointed to the necessity of instituting a comprehensive, collaborative, and cooperating inquiry into the whole question of malignant disease; and that it is a source of great satisfaction to know that at last, though with great difficulty, sufficient funds have been raised to enable the two royal colleges to make, at any rate, a beginning in this wide-reaching and unspeakably important subject.

Mr. Morris's presentation of the cancer situation—although by some it may be looked upon as somewhat too dogmatic—will be, upon the whole, accepted as a fair and unprejudiced statement of facts.

With regard to treatment—excision excepted—the paper of the British surgeon is a confession of failure. Finsen's light and the *x*-rays may now be said to have proved their efficacy in the treatment of rodent ulcers.

The most strikingly insistent part of Mr. Morris's paper is that in which he declares our ignorance as to the cause, nature, and curative treatment of cancer, and the necessity of instituting a comprehensive inquiry into the whole question of malignant disease.

The researches of various investigators in different parts of the world has undoubtedly done much to pave the way to the final solution of the cancer problem, but it is just as certain that the theories advanced with respect to the cause of cancer are far from being conclusive, and are, in fact, as yet no more than theories.

At present there is a crying need of instituting inquiries in the manner suggested by Mr. Morris. The Medical Record on several occasions has proposed that the scientific investigators of civilized nations should lay aside all spirit of emulation and self-glory, and should work together for the good of mankind, to endeavor to remove the awful scourge of cancer. But if this scheme be impracticable, American scientists at least should see that they are not left behind in the race. The rich men of this country have shown themselves in a high degree willing and eager to advance the cause of education and science, and now, by supplying the funds to prosecute under the most favorable auspices the search for the origin of cancer, they have a splendid opportunity of ridding mankind of, perhaps, the most terrible malady to which it is subject, and of conferring lasting honor upon their country and themselves.

THE FINGER-NAILS AS A MEDIUM FOR THE TRANSMISSION OF TUBERCULOSIS.

It is now universally admitted that much can be done in the treatment of tuberculosis by hygienic measures and improvement of the general nutrition, but it is a self-evident fact that if this disease is measurably to be suppressed such a result must be attained through preventive measures. For the successful application of the latter it is essential that the channels of communication should be known, in order that they may be effectively closed and the dissemination of the infection thereby controlled. Tuberculosis, particularly of glands, bones and joints, is common among children, and it is to be surmised that such local lesions must be of local origin.

In accordance with current conceptions, the disease can no longer be considered hereditary. In the exceptional instances of congenital tuberculosis, in which transmission occurs from either parent to the fœtus, the mode of infection is precisely the same as during extrauterine existence, except that instead of occurring through the intermediation of the air, water, or food, the conveyance is more direct, through the blood and lymph, or through cellular implantation. After birth the principal source of infection resides in association with others suffering from the disease. An additional danger is encountered when the child is able to crawl and creep, in conjunction with the bad habit so common among children of introducing all sorts of things, including the hands, into the mouth. Tubercle bacilli have repeatedly been found in the dust of rooms and corridors, especially in houses occupied by tuberculous persons, and Drs. Kornel Preisich and Alader Schütz, in an article in the *Berliner* *klinische Wochenschrift*, May 19, 1902, adduce evidence to show that the same microorganisms can often be demonstrated in the dirt obtained from beneath the fingernails of children, whence they become a source of danger. The observations were made upon children from six months to two years of age for a period of two and one-half months, during which they were kept indoors a good deal. The dirt from the finger-nails was rubbed upon a sterile glass slide with a drop of sterile bouillon and the resulting emulsion was spread on the slide and was used in part for subcutaneous injection in guinea-pigs. Great importance was attached in advance to the result of inoculation, but it was soon found that a number of the animals died shortly afterward as a result of acute infection. Accordingly, reliance had to be placed principally on the results of staining, as it also developed that the number of tubercle bacilli in the dirt was insufficient for successful inoculation. Sixty-six cases were thus examined, and positive results obtained in twenty-four—21.4 per cent. Of the successful cases there was no history of tuberculosis in five; in two there was a predisposition to the disease, and in one merely a suspicion thereof; in two there was a family or a house history of tuberculosis; in four suppurating bone disease was present. Among the fifty-two unsuccessful cases there was no history of tuberculosis in twenty-five; in five there was a doubtful history, and in seventeen there was a definite history of this character, but in none of these was tuberculosis present in the family at the time. In the remaining five cases tuberculosis existed in the family or in the house.

The results of this investigation emphasize the care that should be taken to keep the finger-nails of children as clean as possible, and also to prevent children from putting their fingers and other foreign bodies into the mouth, and further, the danger, especially to children, from living in a house or a room previously occupied by a tuberculous individual.

BOOK REVIEWING.

In a recent issue of the *Publisher's Weekly* is an interesting and suggestive discussion on the utility of book reviews from a literary, as well as commercial point of view. So far, it seems to have been decided on the affirmative side, although the contrary argument has had a good showing. The purely business aspect of the question receives most attention, as might be expected, and narrows itself to the consideration of the degree of advertising which the book may thus obtain. If criticisms are honest, impartial, and discriminative, the mere cost of a volume weighs very small in the equivalent of returns. With most of the sensational novels of the day the merest notice of their appearance is a most extravagant acknowledgment of their worth.

So long as publishers insist that every new work shall receive attention at the hand of the reviewer and so long as periodicals will acquiesce in such requirements we must expect useless, perfunctory, and slip-shod opinions. The public cannot be blamed for taking the latter at their true worth and for properly estimating the motives which actuate the writers. Almost every new publication that comes to such journals "is the best of its kind, deserves wonderful success, and is destined to make its mark." Thus it happens that the price of the book is paid by the merest machine-made scribble.

On the contrary, an independent periodical seeking only the good of its readers and endeavoring to minister to their real needs must exert its beneficial influence in discriminating the good from the bad and in rendering a candid criticism of the best fruits of an open market.

Judicious criticism always makes itself apparent, and carries with it becoming respect. The reader of a review can seldom fail to be convinced that its writer is candid and competent and that his conclusions are worthy of respect.

On the principle that it is easier to commend than to condemn, most so-called critics yield to the convenience rather than to the justice of the thing, more especially when a prepared notice from the publisher is so ready at hand. The latter may serve its purpose for works on fiction, in which it is necessary to give the plot and laud the author, but in scientific treatises the case is entirely different. In one the prospective buyer seeks only amusement, and in the other instruction. The fulfilment of the latter duty implies the possession of the highest critical sense, backed by thorough knowledge of the subject and a conscientious desire to do strict justice to all parties concerned. Hence it is the practice in all high-class journals to leave the task to experts in given lines, whose verdict shall carry with it the due weight of authority. To the furtherance of such an end, and to give the reviewer the freest possible scope for the expression of his views, he speaks for the paper or magazine rather than for himself, the editor being the only peron who is accountable for the fairness of the transactions. The main questions are, how much a given book differs from others of its kind, what it contains that is new and useful, and what new fields of inquiry have been explored. These, in the judgment of the impartial critic, are of the highest importance, and settle the actual value of the new work for the student. In rendering his decision he must place himself in the position of the reader, who wishes to know through him if it is worth while to add a new volume to his working library.

It is with such ends in view that the Medical Record has endeavored to conduct its review columns, reserving for itself the right to select such works only as are deemed worthy of notice. In this respect it differs from no other first-class periodical, and strives to place criticism on the high plane it should occupy irrespective of the wishes of a few authors and publishers who may think to the contrary. The mere sending of a book to a reviewer in pay for his opinion is the smallest possible recompense that can be given for a most valuable service to author, publisher, and buyer, and to claim for one moment, as has been done by some of the publishers, that the work is not sufficiently advertised by such means, is the height of absurdity. The motives of the reviewer are quite different from those of the book-maker. It is never a question if the volume will sell but if it will fulfil the higher mission of profit to the reader.

TASTE AND THE FIFTH NERVE.

Some years ago Sir W. R. Gowers treated a case of disease which suggested to him strongly that the path for taste reaches the brain by the roots of the fifth nerve, as regards both the front and the back of the tongue. A modern surgical procedure has since supplied the proof that he was correct in thus surmising. The operation in question is the removal of the Gasserian ganglion and adjacent part of the fifth nerve, known as "Krause's operation" for neuralgia, from the distinguished German surgeon who introduced it.

Sir W. Gowers describes the technique of this operation in the *Journal of Physiology* of July 21, 1902, as follows: "It consists in trephining the skull and raising the cerebral hemisphere so as to expose the position of the Gasserian ganglion. As Victor Horsley performs the operation, the ganglion is seized by forceps and torn from the pons, bringing away with it a third of an inch or more of the roots of the nerve. The whole of the nerve is usually removed; it not being practicable to attempt to spare the motor portion. The effect of the complete removal of the ganglion and the roots of the nerve is to abolish all function, to cause anæsthesia in the whole region supplied. In five consecutive cases operated upon in this manner at the National Hospital for the Paralyzed and Epileptic, London, the sense of taste was found to be lost." Sir W. Gowers thinks that these facts constitute strong evidence that all the fibers of taste—at least in most persons—reach the brain by the fifth nerve.

A somewhat curious feature in connection with this phenomenon is pointed out: that no weight can be attached to the results of observations made during the first two or, perhaps, three weeks after the operation. Some surgeons have not found taste constantly abolished by the operation, and Sir W. Gowers draws attention to some sources of fallacy which might account for the discrepancy, one being that mentioned above—the fallacy of too early observation—and another, that the operation may have been imperfectly performed, some parts of the nerve not having been removed. Sir W. Gowers is positive that by some path the fibers for taste do reach the fifth nerve, at least frequently, and pass to the brain by its roots.

It would be an interesting study in physiology to investigate by what route taste impressions reach the fifth nerve, but it is so abstruse and hedged in with difficulties as neither to lend itself nor, perhaps, to commend itself as a subject for experimental research.

A NEW CURE FOR NEURALGIA.

A recent number of *La Nature* publishes a remedy for neuralgia which is said to have been used with good results. Neuralgia proceeds sometimes from a lesion, or functional derangement of the nervous centres, and sometimes from an inflammation of the nerve, and is accompanied by pains peculiarly violent. The complaint is also extremely rebellious to treatment; in many cases no relief can be gained except by the most radical measures.

Dr. Cordier, a surgeon of Lyons, has thought out a mode of treatment based on the fact that in certain cases of obstinate sciatica the nerve has been cut down upon and drawn. M. Cordier thought that if the peripheric network were treated in a similar way, the effects might be as beneficial. In order to distend the network of nerves he has used gaseous injections and insufflations of air.

The ordinary hypodermic needle is sufficient to make the insufflations of air, and a rubber ball will serve as an insufflator, but small bellows, like that of the Potain apparatus, will answer the purpose better. To remove all danger of infection a glass filled with sterilized wadding can be placed between the rubber bulb and the needle.

The needle is then buried in the cellular subcutaneous tissue, when a certain quantity of air, variable according to the locality, is slowly injected. This procedure is followed by a distention of the skin resembling a ball. In order to bring about the distention and elongation of the fine nervous terminations, M. Cordier states that vigorous massage should be practised over and in the neighborhood of the air ball, so that the air may be diffused.

The results of this treatment are declared to have been very successful, according to the initiator of the remedy, who claims to have had but two failures in twenty-five cases of sciatica treated in this way.

THE SO-CALLED "SPOTTED FEVER" OF THE ROCKY MOUNTAINS.

The U. S. Public Health and Marine-Hospital Service directed Surgeon J. O. Cobb, in June last, to proceed to Missoula, Mont., to investigate an outbreak of the so-called "spotted fever" prevailing in that district. Surgeon Cobb's report is published in *Public Health Reports*, August 15. It seems that the disease has been known to the local practitioners of the Bitter Root valley, Montana, for seventeen years, but that the malady has never occurred among the Indians. The disease has always been limited to the spring months, the first cases usually appearing in March, shortly after the first warm days. All clinical experience goes to show that the disease is not contagious or infectious, but is undoubtedly a protozoan disease, as an intracorpuscular parasite has been found constantly present in the blood of each case examined this year. The organism resembles very closely Theobald Smith's Texas cattle-fever organism, and it is very possible, from the knowledge at hand, that this disease is introduced into man in the same way as the Texas fever organism is introduced into cattle, viz., by the tick.

During the past spring the Montana State Board of Health secured the services of Drs. Wilson and Chownning of the University of Minnesota to go to Missoula and make exhaustive investigations into the matter. Thus far the experimental work of these bacteriologists has clearly demonstrated that an entirely new disease has been encountered, and one that has never before been described.

Their investigations prove that the disease is confined to the Bitter Root and Lolo valleys, covering an area of about twenty miles in width and forty miles in length.

After having found an intra-corpuscular organism in the blood of their cases, their object was to find the host. Every patient gave a history or showed evidence of being bitten by the tick, but as hundreds of persons are bitten by ticks throughout this portion of the State, and as a great many are bitten by ticks from this infected locality and comparatively few contract the disease, it was fair to presume that all ticks did not harbor the parasite. This naturally led them to infer that the host was not the tick, but some animal infested by ticks.

It was discovered that the gopher or ground-squirrel, which is peculiar to the Bitter Root and Lolo valleys was infested with ticks, and further research has tended to confirm the presumption that these animals are the carriers of the disease. A full account of the investigations in detail will be issued shortly by Drs. Wilson and Chownning.

Clinically, says Surgeon Cobb, the disease is very old. Besides the bluish spotting of the skin—which has given the affection its name—the conjunctivæ are markedly injected, the tongue is moist and slightly coated, and the face and extremities are puffy and bloated, but the skin does not pit on pressure.

The disease is of an extremely deadly nature, all cases which have occurred this year have terminated fatally, and only two bad cases, with well-marked eruptive lesions, have been known to end in recovery.

Leprosy in Canton.

In *Public Health Reports* for August 8 is a report prepared by Dr. John M. Swan, surgeon in charge of the Canton hospital, concerning the experiments in leprosy cases at Canton by Dr. Adolph Razlag of Vienna.

It appears from this report that Dr. Adolph Razlag applied to those in charge of the Medical Missionary Society's Hospital for advice and aid as to the best means of obtaining unrestricted conditions for the treatment of patients suffering from leprosy. It was decided to render all possible aid to Dr. Razlag, and accommodations, quite isolated from the resident portion of the hospital, were provided for him, and four leper patients were admitted and placed under strict quarantine. Two of these cases were far advanced and about the worst that could be found in the leper refuge of 1,000 inmates. The following outline shows the general course of treatment:

1. Local. General cold baths, followed by bath medicated with potassium permangate, or double-strength solution of calcium sulphide each bath being followed by friction of the indurated surfaces—no massage or subcutaneous injections were used. Abraded or broken surfaces were treated with peroxide of hydrogen, sozoiodol, Fowler's solution, solution of zinc chloride, ichthyol ointment mercurial ointment, or chrysarobin, the strength and application of these remedies varying according to the symptoms present.

2. Internal or constitutional. Excretory organs kept active, special attention paid to digestive disturbances, administration of arsenic and ichthyol in pill form, ammoniocitrate of iron and strychnine, sodium iodide, and sodium salicylate, the remedies being pushed to their full physiological effect.

It is claimed for this treatment that its effects were obviously beneficial, and that after six months' course of this routine the patients were better in every respect.

Dr. Swan, who is himself an authority on Oriental diseases, says: "As a result of repeated observation of Dr. Razlag's work on behalf of these patients, we may conclude that lepra is unquestionably largely amenable to treatment. Treatment is practically symptomatic, and should generally be continued for five or six months. Success depends on method, strength, and effective application of the remedies used. Each case must be studied and symptoms met in proper order. Sudden changes in the weather affect course and progress of disease. Closure of wounds increases the eruption temporarily." It would thus appear that leprosy may not be the absolutely hopeless disease which it has been so long considered. No radical cure is claimed for Dr. Razlag's treatment, but it is asserted that the worst case may be cured to such an extent as will allow perfect liberty of the patients. If this can be done, a great advance will have been made, and the final results of Dr. Razlag's treatment will be awaited with much interest.

The Hearing of School Children.

The health of school children is rightly now considered to be of paramount importance. Most civilized countries have a more or less efficient system of school inspection by medical men. New York and certain other cities of the United States are in the van in this movement. Of all the complaints, perhaps, to which the young are subject, none are more serious or more frequent than ear affections. Defective hearing is far more common than is generally supposed, and less attention is usually paid to it than its gravity demands.

According to the *Medical Times and Hospital Gazette*, at a special meeting of the Otological Society of the United Kingdom, held on April 14, of this year, the report of Mr. Arthur Cheatle on the examination of the ears of a thousand school children was read. Out of this number the ears were normal in only 432—or under 50 per cent. Middle ear disease was that with which the majority were affected, the numbers being—external ear, 49; middle-ear, 518, and internal ear, 1. The test used by Mr. Cheatle was the whispered voice at eighteen feet, and the hearing was found to be more or less deficient in 520. Eighty-seven children were found to be suffering from chronic middle-ear suppuration. Of these children 71 had adenoids. The number of cases of deafness from post-suppurative conditions was 247, and of these 171 had adenoids. There were 166 cases of non-suppurative middle-ear deafness; of these 141 had adenoids. Adenoids were present in 434 children, and of these aural trouble was present in 394. Only 40 had normal ears.

This is a seriously alarming state of affairs, and as the writer in the *Medical Times* remarks, it is by no means creditable that the two greatest countries of the world—Great Britain and America—should have so little thought for the aural well-being of their children. The remedy suggested is that otological specialists should be attached to all large general hospitals, and that aural surgery should be included in the curriculum of the medical student.

Christian Science a Business Not a Religion.

In refusing to grant a charter to the First Church of Christ, Scientist, at Philadelphia, Judge Arnold, of the Court of Common Pleas gave as a reason the fact that one of the duties of members of the so-called church is the circulation and sale of the books of Mary Baker G. Eddy, and that it is, therefore, a corporation for profit. This is not the first time that the First Church of Christ, Scientist, has been refused a charter in the city of Philadelphia. Five years ago such action was taken by Judge Pennypacker, on the ground that Christian Science is a violation of the law of 1874 as comprising the practice of medicine without due legal authorization. Ex-Judge Beeber, to whom the present application was referred as master, recommended refusal, for the reason that the congregation teaches the doctrine that disease does not exist really, and this teaching is contrary to public policy, as shown in the laws of the State, which recognize not only the existence of disease, but also its infectious and contagious character. Judge Willson, who sat with Judge Arnold during the argument upon the application, held that Christian Science doctrine, as teaching that it is unnecessary and inadvisable to employ approved methods recognized by medical practitioners, is pernicious.

News of the Week.

Col. Smart Ordered to Manila.—Col. Charles L. Smart of the Medical Department of the Army has been ordered to Manila as Chief Surgeon of the Department of the Philippines. Since the return of Gen. O'Reilly, now the Surgeon-General of the Army, there has been no chief surgeon of the military force in the Philippine Islands, the duties of that officer having been performed up to a recent time by Col. Maus.

Retirement of Dr. Lippitt.—Assistant Surgeon Thomas McCormick Lippitt of the navy has been placed on the retired list on account of disability incident to the active service. Dr. Lippitt was the surgeon of the marines sent to Pekin in 1900 to guard the United States legation. Dr. Lippitt was wounded then, and never fully recovered from the injury and subsequent illness caused by the privations and hard work of that trying time. For gallantry displayed during the siege Dr. Lippitt was advanced, numerically, in his grade. He was born in Virginia and entered the naval service from that State in June, 1898.

Virchow's Successor.—Dr. Johannes Orth, Professor of Pathological Anatomy at the University of Göttingen, succeeds the late Prof. Virchow in the chair of Pathological Anatomy at the University of Berlin. Prof. Orth was for many years Prof. Virchow's assistant.

Vaccination of College Students.—A freshman who had just entered Syracuse University was taken wih smallpox. He was removed at once to hospital, but the chancellor has ordered that every one of the two thousand students submit to vaccination.

Provocation to Hydrophobia.—The question of the etiology of rabies is likely to be made the subject of a judicial inquiry, if the suit of a Niagara Falls man against a chemical company ever comes to trial. A man of that town has brought suit against the Acker Process Company to recover $25,000 damages for the death of a son by hydrophobia. The plaintiff alleges that the dog that bit his son went mad because it ran through a pool of waste chemicals thrown out by the defendant company, which is a manufacturer of caustic soda. The company throws its waste material on unoccupied lands. The rains spread the waste, and it has been said that a number of dogs have been burned severely by running through it. This, no doubt, makes the dogs "mad," but is hardly sufficient of itself to drive them rabid.

Report of the Yellow-Fever Commission.—The commission which has been studying yellow fever in Vera Cruz has confirmed in every respect the findings of the medical officers of the U. S. Army in Havana. The commission attributed the prevalence of yellow fever in Vera Cruz to the custom of the Mexicans in gathering rain water for drinking purposes in which the yellow-fever mosquitos were bred in great numbers. The sanitary commission appointed by the Mexican Commission to coöperate with the United States Public Health and Marine Hospital service had been convinced on this point, and a war on the water barrels had reduced yellow fever 50 per cent. As a consequence of the discoveries made, Vera Cruz will adopt a new system of water supply, which will abolish the water barrels altogether, and thus get rid of the mosquito and the yellow fever.

An Argument for the Army Canteen.—Brig-Gen. Funston, in his annual report of the Department of the Colorado, declares that the anti-canteen legislation of Congress has lowered the discipline of the army, ruined scores of good soldiers, and enriched saloon-keepers, gamblers, and dissolute women. His report announces a deplorable increase in offenses, particularly desertion, which he attributes partly to the abolition of the canteen and partly to garrison life restrictions of men returning from field service. Concerning the former, he says that "since this action was taken saloons of the lowest type have been established just outside the boundaries of the various reservations. Their proprietors are in almost every case unprincipled scoundrels, who leave nothing undone to debauch the soldiers and obtain their money. Being in all cases outside the limits of any city, the proprietors of these resorts are subject to no municipal police regulations, and sell liquor regardless of hours and whether the buyer is already intoxicated or not. Gambling is universal in these 'dives', and they are frequented by dissolute women. The soldier, whose desire for a drink would ordinarily be satisfied by a few glasses of beer in the canteen of the post exchange, goes to one of these resorts and does well if he escapes before he has spent or gambled away all his money, overstayed his leave, or engaged in an altercation. As a rule, the local authorities regard the existence of these places with indifference or approval, as it causes the soldier to spend his money in the community. The efficiency of the army or the ruin of a good soldier is nothing to them. There can be no reasonable doubt that most of the trials by general court-martial and summary courts, at least so far as this department is concerned, are directly traceable to this cause." This is the statement, by one who knows, of a condition which has been brought about by the impractical striving after ideals of well-meaning but ignorant enthusiasts. Similar testimony is presented by Gen. George M. Randall, commanding the Department of the Columbia. In his annual report to the adjutant general of the army, he says that "there was a considerable increase over the preceding year in the ratio of trials by court-martial to the average of enlisted strength. It is believed to be due in part to the large number of recruits, but in part also to the abolition of the sale of beer at post exchanges."

Sick Immigrants Barred from the Health Board's Hospitals.—Health Commissioner Lederle has served notice on the Commissioners of Immigration at this port that the Health Department intends to terminate the contract by which it agreed to treat in the city hospitals all immigrants arriving at New York and found suffering from contagious diseases. The reasons given for the cessation of the contract are overcrowding in the municipal hospitals, the danger of infection in transit from Ellis Island to the foot of East Sixteenth street, difficulty of treatment, owing to the immigrants' ignorance of the English language, the annoyance to other patients because of the unclean personal habits of most of the immigrants, and the injustice to the city in raising its percentage of infectious-disease patients. The records of the Health Department from January 1, 1898, to September 10, 1902, show that the department received from the Commissioner of Immigration at the port of New York 1,405 cases of contagious disease, and these patients were accompanied by nearly 1,000 persons who had been more or less exposed to the various diseases. By virtue of the contract with the U. S. Government the Department of Health receives from each patient or accompanying person $2 per day, and so has been receiving in the aggregate, in recent years, from

$20,000 to $30,000 per annum for performing this work.

Specific Treatment of Scarlet Fever. At the German Congress for Internal Medicine, which met at Carlsbad last week, Dr. Moser of Vienna read a paper, in which he reported the results of treatment of some four hundred cases of scarlatina with an antitoxic serum. He claimed to have had a mortality of only a little more than 8 per cent., whereas the average hospital mortality from scarlet fever during the two years that he was conducting his experiments was about 17 per cent. The Viennese health authorities have approved of the serum, and will supply it gratuitously for the treatment of the children of the poor.

Dismissed for Striking a Patient.—One of the internes of the Emergency Hospital, Washington, had recently to treat a young man brought to the hospital suffering from acute arsenical poisoning. The doctor pumped him out as quickly as he could, and was trying to insert the pump again to complete the work when the patient, still unconscious, shut down on his finger and bit it fiercely. In great pain, he struck the patient a hard blow with his left hand in order to cause him to open his mouth and release the finger. The man recovered and left the hospital none the worse for his blow and making no complaint. When it became known that he had struck a patient, the young physician was dismissed on the charge of having broken a hospital rule in so doing. If the facts are as reported, it would seem that the interne was rather severely punished for what was probably a reflex act of self-preservation.

The Stillman Infirmary, a hospital for Harvard students erected by Mr. James Stillman of this city, was opened in Cambridge on Thursday of last week. The appointments of the infirmary are thoroughly modern, in both medical and surgical departments. Each student patient will have the privilege of being attended by his own physician. The hospital is not endowed, and the question of its support is not yet answered, but it is thought that a sort of sickness insurance fund will be created by the payment of a certain yearly sum by each student. This payment will secure free hospital treatment in case of sickness. The assessment will not be compulsory, but one who does not pay it will be charged for care and treatment in case he is ever obliged to enter the infirmary.

Medical Society of the State of Pennsylvania.—At the annual meeting, held at Allentown, September 16, 17, and 18, the following officers were elected for the ensuing year: *President*, Dr. William M. Welch, Philadelphia; *Vice-Presidents*, Drs. H. H. Herbst, Allentown; G. F. Bell, Lycoming; G. W. McNeal, Allegheny; S. P. Heilman, Lebanon; *Secretary*, Dr. C. L. Stevens, Athens; *Assistant Secretary*, Dr. J. B. Appel, Lancaster; *Treasurer*, Dr. G. W. Wagoner, Cambria; *Trustees*, Drs. T. D. Davis, Allegheny; H. G. McCormick, Lycoming; J. M. Livingston, Lancaster Dr. Wagoner having been nominated for Treasurer, resigned as a member of the Board of Trustees, and Dr. L. B. Kline of Columbia was chosen in his place. York was selected as the next meeting place, and the time the fourth Tuesday in September, 1903.

The Alpha Omega Alpha Society. There has recently been established in the senior class of the College of Physicians and Surgeons of Chicago what the organizers believe to be the first honorary society in a medical school in this country. The object of this fraternity is to maintain a high standard of thought and action in medical schools and in the profession, and to encourage the high ideals supported by earnest students and practitioners everywhere. Not more than thirty names are to be considered for election from any one class of over two hundred students, and the proportion can never exceed one-sixth of the class. The constitution will allow chapters in other medical colleges of the highest standing only, and honorary members may be admitted who shall, in every case, be men or women eminent in the profession. The badge is a key to be worn as a watch charm, designed after the manubrium sterni, upon which are engraved the three Greek letters, Alpha, Omega, Alpha. The Charter members are Messrs. W. W. Root, E. S. Moore, B. Thomas, C. L. Williams, G. H. Howard, W. H. Moore, W. M. Wochos, J. E. Haskell and M. W. Hall.

The President's Injury. At the time President Roosevelt met with the trolley accident in Massachusetts, he received a number of bruises in various parts of the body. All of them healed without suppuration, but one over the tibia gave him more or less trouble and finally showed evidences of a fluid accumulation. This was aspirated while the President was in Indianapolis and a quantity of fluid was evacuated, which, when examined, appeared to be serous, without any purulent admixture. The inflammatory symptoms persisted, however, and there seemed to be a reaccumulation of fluid. Four days after the first operation a consultation was held in Washington, Dr. Shaffer of New York having been called to advise with the other surgeons. A statement given to the press on Sunday by Secretary Cortelyou was that "the increase in local symptoms and a rise in temperature rendered it necessary to make an incision into the small cavity, exposing the bone, which was found to be slightly affected. Thorough drainage is now established and the physicians feel confident that recovery will be uninterrupted. The operation was performed by Surgeon-General Rixey, assisted by Dr. Lung, and in consultation with Surgeon-General O'Reilley and Drs. Shaffer, Urie, and Stitt." Judging from this and other statements of the President's injury which have been published from time to time, it is probable that there was a subperiosteal effusion at the time of the injury. This was not absorbed, but formed a serous collection lifting the periosteum from the bone over a small area.

Cholera in Egypt.—During the week ending September 27, there were 4,421 new cases of cholera and 3,902 deaths reported in Egypt. The epidemic is believed to be declining, and no apprehension is felt that the Egyptian Medical Congress, to be held in Cairo in December, will have to be postponed on account of the cholera.

Obituary Notes.—Dr. Edward Miller Cameron died at his home in this city on September 28, at the age of seventy-three years. He was a graduate of the College of Physicians and Surgeons in the class of 1853, and was consulting physician to Trinity Hospital.

Prof. Willard Humphreys, the head of the Department of German at Princeton University, died on September 26, from an overdose of chloral, taken to quiet an aching tooth. He was born in Brooklyn in 1867, and was graduated in medicine from Columbia University in 1888. He did not practice medicine.

Dr Edmund K. Perrine died at Philadelphia on September 18, at the age of forty years. He was graduated from Jefferson Medical College in 1883 and continued his studies abroad

Dr. B. J. Stokvis, Professor of Pharmacology and General Pathology at the University of Amsterdam, died on September 29, at the age of sixty-eight years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ELECTION—PROFESSIONAL INCOMES—PROSPECTS OF STUDENTS—HOSPITALS AND NURSING HOMES—SCIENTIFIC AND SANITARY CONGRESSES.

London, September 12.

After all, we are in for a contested election for the General Medical Council. Just as I sat down to write to you my voting-paper arrived, and it has to be returned on or before this day week.

Mr. Joseph Smith is, of course, within his right in contesting the seat, but I feel inclined to join in the regrets generally expressed that he should take the step on this occasion. Sir Victor Horsley has worked with such zeal on the Council that to oppose his re-election seems factious on the part of a professed reformer, and it would certainly be ungrateful for the constituency to reject his further services. I do not approve of all his views, and may sometimes question the wisdom of his method of enforcing them. But his zeal for reform is beyond dispute, and he has put fresh vigor into the Council. Mr. Smith claims as principles a couple of rather inconsequent assertions. He says the seat ought to be filled by a general practitioner, and that the late Sir A. Clark thought so. The act does not give it to a general practitioner, but to a registered practitioner, and to be on the register is the only legal qualification. How a man practises has nothing to do with it. Sir A. Clark's dictum was only an opinion. Mr. Smith's other principle is "topographical representation," by which he means the division of the country into three electoral districts. Londoners will occupy two seats if a countryman be elected, as, he holds, should be the case, but, as he lives only in the suburbs, his election would scarcely further the "principle."

The winter session is close upon us, and teachers are hoping for large entries. The so-called students' numbers of the journals have appeared professedly as helps to decide on the choice of a school, though it is doubtful if students or parents consult them. They usually give some vague advice, and tell students that it is a noble profession, and so on. This year the *British Medical Journal* ventured an estimate of the average income that might be expected by the general practitioner, and put it at £400 to £500. The estimate was copied into several daily papers, and has produced a large crop of correspondence, teeming with ridicule and indignation. The general practitioners, who ought to know, declare that only a small proportion of their number earn so much even after years of arduous work. The competition brought about by the overcrowded state of the profession is, they declare, so great that it is a cruelty to induce men, by inflated estimates, to enter it. Disillusion must follow, and bitter will be the disappointment of those who have been induced by such misstatements to spend their best years in unremunerative labor.

One correspondent, after forty years' work, says, let who will enter the profession, but let their eyes be open. There are, he says, two courses: "(1) The golden rule; the good samaritan—poverty the reward. (2) Self-seeking, a thick skin, indifference to others—ease and comfort the reward." This is by no means the most severe estimate.

Other correspondents have turned their attention to the causes of the poverty in the profession. Of these, hospital abuse is the first, and it is well that this question should be discussed by the public. So far no very important suggestions have been made, and certainly no novel ones. Inquiry into the circumstances of applicants is strongly recommended by some, while others say that committees and managers often resent the proposal, and certainly the candidates for relief do not admire it.

Complaints have been made that well-to-do patients will go to hospitals to undergo operations. Various writers have accounted for this by declaring they could not meet the operator's fees, and the heavy cost of nursing homes. The question is asked who is well-to-do? Is a family man well-to-do with £300 or £400 a year? He can pay his doctor in an ordinary way, and does so. But when it comes to a serious operation, a year's income may have to be sunk. One correspondent relates that he was advised to go into a nursing home. As a favor, he was received at seven guineas a week, paid the surgeon one hundred guineas for operating, besides fees for assistant surgeon, anæsthetist, and for subsequent attention. The home also charged numerous extras, such as drugs, dressings. Altogether his relief cost him nearly £200, besides which he was advised to take a month in the country. How could he do this on an income of £300? Only by incurring a debt which he is now struggling to pay off. So far as the nursing homes go, I can corroborate his statement. Most of them charge from six guineas a week upward. In fact, though nominally established to meet the middle-class sufferers, they are generally as expensive as first-class hotels, and the question arises whether a patient of this class would not do better in his own home—the expense of which is, of course, going on all the time. While writing this I have been interrupted by a patient who has just come out of a "home," and says he was quite satisfied. The cost averaged thirteen guineas a week. He could afford it. It is sometimes suggested that less prosperous patients might be admitted to our large hospitals at a moderate charge for board and lodging. That would be better for the hospital than empty wards. Surgeons in constant attendance at the hospital, as many juniors are, would be able to take such a patient at a lower fee, as entailing less trouble. Against this it is urged that too many already are admitted without pay, and that it would open the door to wider abuse. That may be doubted, but it is also urged, and truly enough, that the public go on subscribing without caring how the funds are spent, or whether the sufferers are deserving or not.

One writer gibes at the clergy as fond of posing as almoners with other men's money, and relates that when asked by such a one to give his services to a charity replied that he could not afford to do so, but would willingly contribute to a charity for marrying people without paying the clergyman.

The British Association for the Advancement of Science was opened on Tuesday. The presidential address of this peripatetic society—the mother of the British Medical and other associations—is always looked forward to as an interesting event. Belfast was the meeting place this year, as it was twenty-eight years ago, when the late Professor Tyndall presided and defended Darwin in an address abounding in rhetoric. This year Professor Dewar is president, and in his address, besides a statement of recent researches on cold, and the attempt to reach an absolute zero, he brought before his audience the inadequate equipment of this country in chemical science, comparing the antiquated adherence to rule of thumb of our chemical manufacturers with the enterprise of Germany. He estimated that German chemical works employ 4,500 trained chemists, 74 per cent. of whom are university men, while British works do not employ more than 1,500, of whom only 31 per cent. are scientifically trained. This accounts for a transference to Germany of trade worth £10,000,000 a year—most of it founded on the discoveries of English chemists, which have not been appreciated here. In the same way our former monopoly of the manufacture of fine glass for optical purposes has passed over to Germany. Other examples might be given which show that these industries depend on science, and that, while Germany spends large sums on encouraging and endowing scientific work, our government ignores it. Professor Dewar appealed to the King, who has displayed much interest in medical research, to exert the influence of the crown in favor of science, and remarked that forty-three years ago His Majesty's father, who had studied the growth of practical science in Germany, foresaw what would be the result, and warned the association that the commercial future of the country depended on the recognition of science.

On Wednesday the sections began work, and anthropology was to the fore, Dr. Cunningham discoursing on giants, who, he said, were feeble in mind and body, and died early—their average life being only a fraction over twenty years.

Another sanitary congress was opened on Tuesday. It was the nineteenth annual meeting of the Sanitary Institute, and was held at Manchester. Earl Egerton of Tatton presided, and over 300 sanitary authorities throughout the kingdom were represented, as well as a number of societies—the total number attending exceeding 2,000. Lord Egerton, in his inaugural address, referred to the condition of town populations as degenerated in size and physical power from the ancestors, who were attracted from the country districts by high wages. The percentage of army rejections for physical disabilities shows that this process is still going on. The evidence of the Royal Commission on physical training led to the hope that its recommendations would be adopted, and thus contribute to the sources of national strength. The training of children and instruction in hygiene were considered by Lord Egerton, who referred to the deaths from typhoid in South Africa, and to the importance of a knowledge of the value of boiling water as a preventive. But, whatever our ignorance of sanitary matters, his lordship said we were far in advance of other European nations, and that even the improvements in continental hotels have been borrowed from us in order to satisfy the requirements of English visitors. He hoped the deliberations of the congress might pave the way to greatly improved sanitary conditions, and to the greater vigor and regeneration of our fellow countrymen. The Health Exhibition of the Congress was opened in the afternoon by the Lord Mayor of Manchester.

Book Reviews.

Death and Sudden Death. By P. Brouardel, Professor of Medical Jurisprudence, Dean of Medical Faculty, Paris, and F. Lucas Benham, M.D., B.S. (Lond.), M.D. (Adelaide). Second edition. New York: William Wood & Co., 1902.

The first edition of this book appeared in 1894, and the present one is much amplified by the addition of new matter by Dr. Benham. The body of the work is so essentially the production of Professor Brouardel that Dr. Benham appears more as an annotator than a co-author. The additions are, however, of much value, and are plentifully described through the text, preserving its continuity and bringing it abreast with later observations on the subjects treated. For the most part they are corroborative of the author's original views, and add especially to the interest of the book in a statistical and demonstrative way. It is fair to say that in its present shape the work is the most exhaustive of its kind, and contains an amount of material which cannot fail to be of value to the student of pathology in search of strange and interesting facts, and to the medico-jurist who is anxious to explain the many problems connected with all the varied forms of sudden death under suspicious circumstances. A remarkable feature of the book is the great number of facts collected bearing upon all forms of unexpected death. But best of all are the lucid pathological explanations for the different phenomena. In the discussion of the latter the reader cannot fail to be instructed and edified, as he will be surprised to learn that certain theories which he has believed to be entirely tenable are without foundation, and certain facts, which he had accepted unqualifiedly, are without substantiation. He will discover that sudden death cannot always be accounted for by post-mortem lesions, and that the exact moment of dissolution may often be a matter of grave doubt. The first chapter deals with this subject, and is a fitting introduction for what is to follow. "We cannot admit in forensic medicine," says the author, "that stoppage of the heart is a certain sign of death," and then follows the argument to prove his position. Exception is also taken to the term "death by syncope," the author adopting the view of Brown-Sequard that life becomes extinct by inhibition of one or other of the primary nerve-centers. The illustrations in point are fatal blows upon the epigastrium, larynx, nostrils, and genital organs. The author is not willing to admit that any single sign of death is absolute under all circumstances, but prefers to take into account a series of phenomena as cumulative proof. It is comforting to learn, however, that there is no real danger of premature burial when a physician can be obtained to certify to the death of the individual. The cases given of apparent death are extremely interesting, and dispose very effectually of some of the pretensions of those fakirs who have so long deceived the believers in miracles. The enumeration of the usual causes of sudden death occupy the major part of the treatise, and are grouped under lesions of the heart, circulatory, cerebrospinal, respiratory, digestive, and genitourinary systems, and those occurring in fevers, hæmophilia, diabetes, uræmia, and alcoholism. The description of these varied pathological conditions is in the highest degree satisfactory, giving the student and practitioner a mass of practical information which we do not remember having seen collected in such form in any work on morbid anatomy. Not the least interesting part of the book is that which follows the body from the moment of death until final dissolution, describing all the different phases of decomposition from the commencement of cadaveric rigidity until "dust to dust" ends the lesson of mortality.

Alleged Cure of Leprosy.—A report from St. Louis states that Dong Gong, a Chinese leper patient at the Quarantine Hospital in that city, has been recommended for discharge as cured by Dr. M. C. Woodruff, superintendent of the hospital. The man was sent to quarantine on November 6, 1901, with clearly-defined leprosy. Dr. Woodruff took charge of the patient, and began a method of treatment which a few months ago caused the patient to show such improvement that the physician said that he believed that the leper would be permanently cured, and he now recommends his discharge. A medical commission has been appointed to examine the patient, and if its report sustains that of Dr. Woodruff, Dong Gong will be released.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Sept 25, 1902

The Iliopsoas Bursa.—F B Lund considers that this bursa has received too little attention in the past, yet it may be involved in osteoarthritis, gonorrhœal infection, or suppurative arthritis of the joint Incision of the bursa affords an easy method for reaching and draining the joint The bursa is best reached by a vertical incision just below Poupart's ligament, between the anterior crural nerve and the femoral artery. When the bursa is connected with the joint a ready diagnosis of the condition of the head of the femur and acetabulum may be made by passing the finger through the opening in the bottom of the bursa. Iliopsoas bursitis should be more often considered in the differential diagnosis of obscure tumors in the groin, and such a diagnosis should be possible in cases in which a hip-joint is known to be diseased, and a tumor suddenly appears in front of the joint, under the anterior crural nerve and femoral vessels, which is very painful and tender, and, perhaps, gives to the palpating finger a sensation of deep fluctuation.

Operative Treatment of Varicose Veins.—J. B Blake holds that the multiple ligature is distinctly less effective than other methods, and that we are left with the choice of an extensive dissection, or a local excision in the thigh, or a combination. Trendelenburg's operation is the type of the last-named class. It consists simply in the ligation of the internal saphenous vein in two places, five or six centimeters apart, in the upper third of the thigh, and the excision of the short intervening portion. It has one object—to interrupt the blood column. It is indicated only in those cases in which, the limb being raised and made free from blood, the saphenous vein being compressed, and the leg lowered, the blood is seen to rush in a wave down into the empty vein the moment the pressure is removed. Trendelenburg's operation does not contemplate the removal of local varix—of veins which have become thrombosed—nor of those which threaten to rupture. While foreign operators have reported excellent results, the writer has not been able to find any printed report of series of cases treated in this country by the Trendelenburg method.

Journal of the American Medical Association, Sept. 27, 1902.

The Inoperable Nature of the Pulmonary Tuberculous Lesion.—H. J. Whitacre calls attention to the excision of pulmonary tuberculous disease, the drainage of tuberculous cavities, the nitrogen-compression method, devised by Murphy, and the treatment of tuberculosis by extensive thoracoplasty. He presents the following conclusions: (1) The excision of the pulmonary lesion is, in the vast majority of cases, both impossible and irrational. (2) The incision and drainage of tuberculous cavities in the lung does not seem to be a justifiable operation. (3) The nitrogen-compression method is a rational procedure in a limited number of selected cases; its application is safe, the effect on the tuberculous lungs seems favorable, and the results reported are encouraging. (4) Thoracoplasty, while based on the same sound principles that give value to the nitrogen method, is an extensive operation, involving great risk to life, and furnishes slight promise of improving the percentage of cures obtained by climatic treatment.

Repeated Small Hemorrhages as a Cause of Severe Anæmia.—J. B. Herrick gives the clinical histories of cases illustrating the fact mentioned in the title of his paper. Most of them were cases of hemorrhoids. He says that the practical lesson to be drawn from such clinical experience is that severe anæmia, threatening life and producing a pallor and weakness equal to that of the pernicious variety, or suggesting some hidden malignant disease, may at times be caused by repeated small hemorrhages, often from a condition as easily recognized and easily remedied as hemorrhoids. This form of anæmia may prove fatal; and cases of a transformation of the type into the pernicious are reported, especially by English writers; and Ehrlich inclines to the belief that the pernicious variety may have its origin in repeated hemorrhages. The careful blood examination, showing the chlorotic or secondary type of anæmia, should give encouragement for immediate measures looking toward a checking of the hemorrhage. The hemorrhage once stopped, recovery, though it may be slow, is generally complete.

Etiology and Treatment of Chronic Cystitis.—A C. Stokes says that the etiology of this affection is essentially a bacteriological problem The germs most frequently found are, in order of frequency, colon bacillus, streptococcus, staphylococcus in several species, typhoid bacillus gonococcus of Neisser, proteus vulgaris, and the tubercle bacillus. The fermentation of the urine has been shown by Melchior and Muller to be rather a result of infection than a cause of cystitis, certain germs producing ammonium carbonate from urea, thus converting the urine into an ammoniacal substance giving an alkaline reaction. The chief germs which do so are the micrococcus of urea, species of the pyogenic germs, and occasionally the colon bacillus and *Proteus vulgaris*. It will be found in a goodly number of cases—perhaps one-half—that the urine is acid, and we may still have the evidences of cystitis present. Treatment embraces the following: (*a*) internal medication; (*b*) washing bladder; (*c*) installation into bladder, (*d*) topical application; (*e*) stretching bladder; (*f*) operation. In the cystitis of gonorrhœa he instills into the bladder a 1 to 5,000 silver nitrate solution, about once in three days, using about 30 c.c., and increases the strength gradually, sometimes reaching 1 to 200. In infections from the colon and tubercle bacilli he has found mercuric chloride to be a very efficient remedy to instill into a bladder which has been washed out clean by some good antiseptic He uses about 30 c.c of a 1 to 20,000 solution, putting it into the bladder once in two or three days, as the irritation seems to allow, gradually increasing in strength. This should never be used in gonorrhœal cystitis, nor silver nitrate in the tuberculous form. In tuberculous cystitis he has often obtained good results from installation of about two drachms of a 10 per cent. solution of iodoform in glycerin, used in the same manner as above.

Medical News, September 27, 1902.

School Life and Insanity.—J. S. Lankford emphasizes the fact that the burden laid upon our children is far beyond the limits of safety. It is a powerful factor in the causation of insanity. The weight must be lightened, or else the children will suffer greatly, and posterity will reap degeneration from the seeds which we are sowing. In order to save our children from this fate, promote their proper mental development, and protect posterity, we must: Reduce the course of study. Develop the body co-equally with the mind. Institute a better classification of pupils, and study individual tendencies and requirements. Use object lessons rather than books · Introduce industrial training as rapidly as possible. The text-books must be abbreviated, or a number must be dropped from the course. Industrial training, perhaps, offers the best relief from the present system of oppression. The writer thinks that we should strive for a system of education which permits and promotes the natural evolution of the whole human creature without undue strain, and which utilizes the best of nature's gifts. Insanity, in many forms, will then materially decrease.

The Importance of Diagnosis in Skin Diseases Considered Generally and as Applied to Particular Diseases.—Isadore Dyer gives three cardinal points to be considered in the diagnosis of skin diseases: (1) The location of the disease is the first point of study; (2) The distribution on the particular region on which it occurs; (3) The arrangement of the component parts or lesions. The lesions themselves must be studied in detail, so as to classify the disease. The writer then sums up the following points in diagnosis, which are valuable as guides: (1) Eruptions which are bilaterally symmetrical are either constitutional in origin or are exposed to the identical local cause on both sides of the body. (2) Parasitic diseases are found on the flexors, preferably, or on the exposed parts of the body. (3) The more chronic diseases of the skin become, the deeper the color, on the other hand, the brighter and more vivid the color, the more acute the disease. Scales are the evidence of chronicity; likewise ulcers and scars. (4) Fluid lesions seldom itch; papular eruptions almost always itch. (5) Single ulcers are almost always syphilitic, trophic, traumatic, or malignant. (6) On the face ulcers are seldom due to other causes than cancer, syphilis, or tuberculosis. (7) The color of eruption on the Caucasian is always important in diagnosis Syphilis is pigmented brown or buff, as its eruptions fade or disappear. Leprosy is always shaded brown or purple. Lichen ruber is always violaceous or white Psoriasis is always pale red, covered with white scales. Seborrhœic eczema is always yellowish red with greasy scales. (8) The odor in skin diseases is important Syphilis, when ulcerating, smells rancid, favus smells mousy; varicose ulcers smell sweet; neurotic ulcers, or those of leprosy, are nauseous, foul and intense, rodent ulcer has a smell of rotting meat.

Bronchial Asthma and Allied Disorders; Their Summer Treatment. Beverley Robinson states that asthma is a symptom of many allied conditions, as a rule, it is explained by none solely The acute dyspnœa should be relieved as rapidly as possible provided always it is done rationally and without causing, immediately or subsequently, avoidable injury to the patient. In general, an injection of morphine and atropine will relieve many urgent cases But there are exceptions Again, inhalation of amyl nitrite often gives great relief. There are also exceptions to be noted here. The writer believes in the great efficacy of iodide of potash. Generally, when the suffering is acute or moderate, it should be combined with Hoffman's anodyne. As to the climate best suited to these cases, experiments must be made with each individual case until the place best suited to his trouble shall be found. If the patient cannot go to Europe, the writer advises sulphur springs in the United States, preferably Sharon or Richfield, or some region of the Adirondacks. As to other treatment, it should be pretty much as it is under the same conditions in the winter. Search should be made for any other trouble—for any sinning agent or organ; and this, when found, should be corrected. In chronic cases, the heart is nearly always affected. Digestive disturbances often accompany bronchial asthma. The food should be simple, wholesome, and well prepared. The drinking water should also be pure and potable. In cases in which there is an interdependence at times of eczema and other cutaneous disorders and asthma, arsenic is the most useful of all remedies, both for the dyspnœa and itching. The writer states that he is chary of both much medicine and much surgery. He believes decidedly in the daily use of all hygienic methods.

New York Medical Journal, September 27, 1902.

The Treatment of Yellow Fever.—J. H. Egbert says that, as soon as the diagnosis is established, we must seek to relax the peripheral capillaries, quicken the portal circulation, and stimulate the emunctories. Diaphoresis must be brought about by blankets, hot drinks, and hot pediluvia. An active cathartic should then be given, and during the continuance of the primary fever, he advises the use of aconite with sweet spirits of niter and acetate of ammonia Hot vapor baths are also of service. If, within a day, the initial fever has not yet subsided, he gives acetanilid and quinine. Opiates are always contraindicated, while nervous symptoms may be combated with bromides, cold compresses to the head, and hot ones to the feet. For remissions, the quinine should be continued, mineral acids given, and the liver and kidneys kept active. Strychnine is an excellent stimulant for depression and general debility. For the third stage, in which the tendency to collapse is so noticeable, we must use the cardiac stimulants, alcohol, sponge the surface of the body with water, and give copious enemas of warm water, to which a little salt may be advantageously added. The latter procedure also stimulates the kidneys. The author advises rigid quarantine of suspected persons He does not regard the mosquito as the only carrier of infection, but claims that the latter is certainly conveyed by fomites.

Placenta Prævia; Its Early Recognition and Treatment.—E. A. Ayres calls attention to the fact that the placental site is more vascular than the remainder of the uterine wall, and that it is also thicker and softer. With thin abdominal walls and lax uterine muscle, the placental edge may be palpated, while if it overlies a portion of the fetal body, palpation of the latter may be obscured, and the fetal heart sounds weakened. The "uterine souffle" is not a safe guide to the location of the placenta. There is also an increase in bulk at the placental site of the uterus. It is possible to palpate the uterus through the rectum, provided an anæsthetic be used. Direct vaginal palpation will generally locate a central implantation. In some cases a diagnosis may be made by the soft boggy or mushy character of the lower uterine segment, accompanied by a marked pulsation. As to treatment, Ayres thinks that in central or marginal implantation the eighth month of pregnancy is the ideal time for the induction of premature labor. Otherwise, in the majority of cases, we must be guided by circumstances, the safety of the mother being the paramount consideration. If the mother can be placed in a hospital and have a skilful physician and nurse constantly at hand, and the pregnancy is before the eighth month, and, particularly where a living child is especially desired, it is just and conservative to delay. Should a severe hemorrhage occur then, it may be better to place the patient in bed, to give morphine until equilibrium is restored and recovery from the immediate loss of blood and shock is secured, and then to proceed to induce labor. Cases of partial implantation seldom call for induced labor. Practically, such cases are rarely recognized before delivery, which is accompanied by a severe initial hemorrhage, which ceases as soon as the head engages.

Pain as a Symptom in Gynecological Disease.—S. M. Brickner says that pain under the conditions implied in the title of his paper may be spontaneous or invoked. It is spontaneous in all acute diseases, salpingitis, perimetritis, etc., and in some chronic affections, especially new growths. Such pain may affect the gait, and causes dyspareunia. Faults of the uterine suspensory apparatus cause pain in the standing position, while pain in the sitting position may be due to hemorrhoids, to affections of Douglas's pouch, or to hypertrophic elongation of the cervix. Pain may be evoked at the examination by the physician. Again pain may be intermittent or continuous, lancinating, or colicky. Its seat naturally varies with the disease. The frequent pain referred to the back is very often due to a tugging on the sacrouterine ligaments or to a laceration or neoplasm of the cervix. Pain in the abdomen, at the level of the pubes, may be ascribed to bladder or uterine disease; or if it is on one side of the abdomen, to some tubal affection. The latter is usually accompanied by radiating pains, due to compression of nerves, and this is very frequent in the region of the sciatic nerve. If there happens to be a descent of the uterus, we will find symptoms on the part of the bladder, dysuria, polyuria, or pollakiuria. If the uterus has fallen back into the cul-de-sac, we shall find symptoms on the part of the rectum, such as pain in defecation, constipation, or tenesmus and the same symptomatology holds true for affections which are localized in Douglas's pouch. The ovarian and tubal affections are eminently painful ones. Acute ophoritis and salpingitis easily occupy the first place. Ovarian neoplasms do not offer any characteristic evidences of pain. What discomfort there is, is due to the weight of the mass. When adhesions form, the picture is changed, and we often have excruciating pain. Prolapsed ovaries are, as a rule, painful. Tubal pregnancy, also, is a very painful affection. Tuberculous peritonitis also has characteristic pains, which differ from those of other affections.

American Medicine, September 27, 1902.

School Vaccinations.—William R. Fisher says that it is not to be supposed that all of the vaccinations which are annually done at the beginning of the school year are successful. There is good reason to believe that continuously a very considerable number of children are attending school who are unprotected by vaccination, although they have presented certificates of the same. In certain rural districts, too, there is no restriction upon admission to school, and the proportion of unvaccinated scholars is probably very high. It has been noticed that the number of primary vaccinations among the applicants for certificates is steadily increasing. Parents defer the vaccination of their children till they are of school age. Thus a large number of young children are left without protection at an age when susceptibility to smallpox is great, and the mortality is high. In the warm season, too, the course of vaccination in human beings is not as satisfactory as at other times of the year. Also, in hot weather, conditions necessary for the production of a high-grade vaccine virus cannot always be secured, nor can a thoroughly active virus be protected from injurious exposure to heat during transportation. So a good many failures in vaccination are met with in August and the beginning of September. Hot weather also favors the development of complications which arise from septic infection. If existing legislation is producing results which the enemies of vaccination can make use of, the sooner it is amended, the better. The power of issuing certificates of vaccination should be restricted to the health officers of the State, city, town, or borough where it properly belongs. They should determine the protection of each individual solely by the existence of the typical vaccination scar. This certain, well-defined sign cannot be forged.

Relaxation of the Synchondrosis of the Symphysis Pubis, Following Normal Labor, Treated by Resection and Wiring.—From a perusal of the literature, B. R. Schenck notes the following chief points concerning these cases which are comparatively rare: Separation of the pubic cartilages occurs much more frequently in multiparas than in primiparas, particularly in women who have borne more than three children. When occuring in primiparas, it is usually in those in the third or fourth decade of life. In a large percentage of cases the separation took place in difficult labors, generally during a tension or forceps delivery. A generally contracted pelvis has most frequently been found. When there is an actual rupture, this often takes place with a loud, cracking sound. When there is relaxation of the ligaments, allowing the bones to slip upon one another, the condition may not be discovered until after confinement, usually when the patient first moves herself in bed. The chief symptoms are pain over the pubic arch, pain while lying in any other position than on the back, and pain and difficulty in walking. Suppuration frequently occurs, destroying the articular cartilages. Duhrssen reports twenty-three cases in which this took place. Simple measures, such as strapping with adhesive plaster, or the application of a tight bandage over the hips usually suffices to keep the tissues in position, until union takes place. When there is no infection, this generally occurs in from four to six weeks. The writer then reports a case in which the loosening of the articulation took place about the fifth month of pregnancy. Dr. Kelly operated eight months after her confinement. He resected the synchondrosis of the symphysis pubis and wired the pubic bones with heavy silver wire. The silver sutures were twisted tightly, thus perfectly bringing together the pubic bones, and the wound was closed with catgut sutures. A retention catheter was placed in the urethra and the patient was strapped down to a Bradford frame. She was kept on the frame five weeks, and in bed two weeks longer, after which she was up and about improving each day. On leaving the hospital, she could walk with no discomfort. There was no callous and no tenderness.

Philadelphia Medical Journal, September 27, 1902.

Leucocytosis in Lead-Workers.—L. Napoleon of Boston gives the results of his study of twenty-four cases of this nature. The longest period any patient had worked before symptoms developed was twelve years, the shortest, six weeks. The variety of work appeared to exercise but little etiological influence, but in all cases in which special care had been taken to cleanse the hands thoroughly before taking food, symptoms developed late, but were always severe. Three of the cases gave a leucocyte count below 10,000, and the remainder gave counts varying between 10,000 and 25,500. The number of red cells and the percentage of hæmoglobin bore no constant relation to the number of leucocytes present. In this series of cases the average number of leucocytes was 12,600; the greatest number being 25,500, the smallest, 4,000. A moderate reduction in the number of erythrocytes to 3,500,000, is the rule, yet in severe cases they may fall below this number. The hæmoglobin fluctuated between 32 and 85 per cent. No constant ratio was found between the number of red cells and the percentage of hæmoglobin. A rather high grade of poikilocytosis was noted.

An Additional Case of Tumor of the Brain, Localized Clinically and by the Röntgen Rays.—Charles K. Mills, G. E. Pfahler, and J. B. Deaver were all interested in this case, which Mills reports. The patient was a woman twenty-one years old. Her symptoms began apparently three years before she presented herself to the writer. While going down stairs one day she felt her left leg give way. She was not unconscious, but the left half of her body was numb, and her speech was somewhat thick. This condition lasted about an hour. From this time on she had attacks of weakness and numbness in the left arm, leg, and trunk, and sometimes in the face and tongue. At the end of the first year she began to have very severe and almost continuous headaches. She gradually lost power in the left arm and leg. She finally lost the sight in both eyes. Her paternal grandmother died of cancer of the breast; her paternal aunt of cancer of the stomach, and her father's cousin probably of pyloric cancer. A skiagraph was taken of the patient's head, and a shadow was detected. This was definite, but not very marked. Its deepest portion corresponded to a point just in front of the central fissure. Operation was performed, and a large tumor removed, which proved to be a spindle-cell sarcoma, and was encapsulated. There were various points of interest about this case: Astereognosis, ataxia, and paresis were all present, but as the separate regions of stereognostic perception, the so-called muscular sense, and the representation of movements, were all involved, no conclusive inferences could be drawn. A point of physiological interest was the entire absence of impairment of cutaneous sensibility, although the postparietal region was distinctly involved. This may be accounted for either on the theory that the limbic lobe is the sole cortical seat of the representation of cutaneous sensibility, or that a lesion must be, in part at least, subcortical in order to cause persisting cutaneous anæsthesia, or, finally, that the lesion must be bilateral in the postparietal region in order to bring about its effect. The writer concludes from the study of this case that as soon as a brain tumor is clearly diagnosed, if presumably it is in an accessible area, operation should at once be performed. A Röntgen ray investigation should be added to the other methods of making a diagnosis. Large openings in the skull should always be made. The operation should be osteoplastic, in order not to leave a permanent opening in the skull and to add to the chances of maintaining the vitality of the bone flap. Preparation should always be made to perform a Crile operation for temporary clamping of the carotids as soon as hemorrhage becomes threatening. The operation in some cases should be done in two stages, the propriety of this procedure being determined by the circumstances attending the first operation.

The Lancet, September 20, 1902.

Death from the Bursting of a Tonsillar Abscess.—A. Lyons reports the case, his patient being a man of twenty-eight years. About half an hour after admission to the hospital he coughed and became cyanotic. Before aid could be summoned he was dead. Autopsy showed that a large abscess in the left tonsillar region had burst, and that considerable pus had gotten into the upper half of the larynx. The author knows of but one similar case.

Mucin and Malignancy; Facts and Theories.—W. Stuart-Low, having observed in a series of fifteen cases of malignant growths a deficiency of mucus, which condition he calls hypomyxia, was led to give mucin internally in several cases. He has obtained somewhat encouraging results, but as yet nothing positively definite. He has his patients abstain from the use of salt and tobacco, which two factors he regards as of importance in the etiology of malignant growths.

Persistent Hereditary Œdema of the Lower Limbs.—Two cases are reported by H. D. Rolleston of a brother and sister, aged thirteen and sixteen years, respectively. The œdema was permanent as long as they lived ordinarily, but became more marked after exercise or a bath, and disappeared after a rest of some days in bed. It was troublesome only from the size and weight of the legs, but caused no pain or other discomfort. The mother had the same condition, but five other children were free therefrom. The blood condition in both children was normal, except that there was in the differential count a diminution in the polymorphonuclears, and a corresponding increase in the lymphocytes and mononuclear forms. No treatment, except position, appeared to have the slightest effect. Such cases have generally been regarded as hereditary angioneurotic œdema, but the author denies that his own patients belong to this category. He rather considers them as presenting features suggesting Raynaud's disease and erythromelalgia, but differing from them in many particulars. He offers no theory for the underlying cause of the œdema.

Occlusion of the Lateral Sinus and Internal Jugular Vein an Essential Part of the Method Employed by Nature, and by the Surgeon in Imitation of Nature, for Arrest of Acute General Infection Having Its Origin within the Temporal Bone.—This paper is by C. A. Ballance, who has accompanied his suggestions with a profuseness of quotations from ancient and modern writers, medical and lay. He believes that the surgical treatment should be the same whether the disease has had its origin in an acute or in a chronic inflammation, and that the dealing with the inflamed sinus and the inflamed vein in a manner comparable to the proper surgical treatment of acute inflammation in other parts of the body by free incision or ablation is not only not dangerous but highly beneficial and curative. When it has been decided to deal with the vein before beginning to operate, the operation on the vein should precede that on the temporal bone, and when operation on the vein is first decided upon during the course of the temporal bone operation, it should be forthwith carried through without waiting for the completion of the operation on the sinus region. The vein when not thrombosed is exposed in the neck about the level of the cricoid cartilage, and the surgeon, tying its tributaries and dividing them between two ligatures, should remove it completely up to the bulb. Ablation of the vein is better than ligature. It involves ligature of the tributary veins, and as the line of incision involves the external jugular that vessel is also necessarily tied. In cases of thrombosis of the internal jugular, the ablation will begin at its junction with the subclavian, and it will be no difficult task in these circumstances to find on its inner side, lying on the scalenus anticus, the vertebral vein and to ligate and divide it also.

The Cancer Problem.—This question is discussed by W. V. Shaw, who starts with the thesis that malignant tumors are characterized by cell proliferation that in its biological relations enters into opposition with the physiological tissues from which they are derived. That the life-history of cancer cells is atypical cannot be doubted when the nuclear changes in these cells are studied. Abnormal mitotic figures are extremely common. Asymmetrical division of the nucleus is frequently observed. In certain forms of sarcoma giant cells are a prominent feature. Hyperplasia of the nucleus and hyperchromatosis of certain mitotic figures are also characteristic of these new growths. These facts point to changes in the life-history of the cells. Again, in carcinomata certain bodies have been observed in constant and close relation with the nucleus of the cancer cells. Some have considered these to be parasitic organisms causally connected with the changes referred to above. Others claim that these are degenerate portions of the nucleus or some endogenous structure formed from the nucleus. Assuming this latter explanation, these bodies give a further indication of the abnormal protoplasmic activity of the cell. How, then, do the above nuclear changes influence the life-history of the cell? To the nucleus alone is assigned the perpetuation of the type and characteristics of the cell from generation to generation, and when any alteration takes place in the nucleus there are corresponding changes in the cell. The nucleus plays an important and controlling part, not only in the process of cell-division, but in the functional activity of the cell. Recent experiments have shown that the stimulation of the ova of certain lowly-organized animals will cause the multiplication of cells and the ultimate development of free swimming larvæ from such ova without previous fertilization of the ova by spermatozoa. Adult organisms do not develop, but larvæ, capable of independent existence, can be produced. This result has been obtained by acting upon the ova with strychnine, and also by mechanical agitation of the ova. The multiplication of cells in these larvæ is comparable with the attempts at reproduction of tissue in partially damaged structures, of which the giant cells in tubercle and the vascular connective tissue of healing wounds are examples. The growth of cancer cells is then to be looked upon as an effort of reproduction in damaged tissue, the incidence of the damage falling upon the nuclear structures. This damage alters the nature of these structures so that the vegetative functions of the cell run riot, and the cells become parasitic toward the organism in which the growth is taking place. The nature of the changes in the cancer cells and their life-history thus becomes the important point from which the origin of the cancer process must be determined. What is the cause of this vegetative activity? Is it an initial damage to the cells, in response to which there is an over-active attempt at repair? The peculiar frequency of such disease in organs once active but now undergoing involution would suggest this explanation, and also the frequent origin of malignant growths in damaged tissue further supports this view. This is in accordance with Weigert's observations on the over-production of damaged parts in the process of repair. Hence, in considering the etiology of malignant growths, the causation of this vegetative activity must be investigated. It may be chemical, as in the experiments with strychnine referred to above, or it may be biological, as in the theories that have been advanced as to the microbic origin of cancer. The actual epithelial cells are the source of the infective process, as shown by the reproduction of the type of cells in secondary growths, and the penetration of the surrounding tissues by the epithelial cells.

British Medical Journal, September 20, 1902.

The Differential Diagnosis of Yellow Fever and Malignant Malaria.—George C. Low, after summing up the common symptoms of these two diseases, declares that it is fortunate that we possess an almost decisive method of at once determining between the two diseases—namely, the examination of the blood for the malarial parasite. Quinine must not have been administered before the blood examination is made. Therefore, it is of extreme importance to examine the blood carefully, especially at the commencement of an epidemic, when doubt may exist as to the nature of the disease. Post mortem, the diagnosis is simple. The presence of the characteristic malarial pigment and of parasites localized in the brain, spleen, or gastric mucosa, at once tells that the case is one of malaria, whereas in yellow fever these are absent, and the liver shows the typical fatty degeneration.

The Prophylaxis of Sunstroke.—Andrew Duncan gives an account of his personal experience with sunstroke in India. He had four attacks. After reading an article on this subject by another sufferer, he followed the advice contained therein, which was as follows: Since no one gets heatstroke from the great heat of furnaces in an arsenal, it is concluded that not the heat rays, but the actinic rays of the sun are the cause of sunstroke. Thus the body is treated as the photographer treats his plates, and is enveloped in orange-colored garments. Whenever the writer had a march to perform in hot weather, he wore an orange-yellow shirt, lined his helmet with orange-yellow flannel, and had a pad of the same color stitched into his coat down the back. He never again felt the effects of the sun. He adds that as a further precaution the helmet might be lined with a layer of tinfoil.

The Affiliations of Yellow Fever.—James Cantlie thinks that perhaps we have looked upon yellow fever too much as a disease wholly unaffiliated with diseases which present many clinical symptoms in common. The most notable of these ailments affiliated in symptoms and even in signs with yellow fever, are: (1) Weil's disease; it closely resembles a mild attack of yellow fever; jaundice is of constant occurrence, appearing about the same period of the illness as in yellow fever; the post-mortem signs are alike in many respects. (2) Acute yellow atrophy of the liver is pathologically allied, in some respects, to yellow fever, in this disease, as in yellow fever, the nature and cause of the poison is unknown; the jaundice, however, appears before the pyrexia, whilst the opposite obtains in yellow fever. (3) Bilious remittent fever presents many symptoms akin to yellow fever, and especially in the fact that the so-called jaundice in both diseases is due not to biliary diffusion, but to modified hæmoglobin, which, being free in the blood, is deposited in the skin, etc.; the former disease is especially prevalent in the area in which yellow fever exists. (4) Bilious typhoid is also a term which serves to confuse our nomenclature; it may well be asked whether the "typhus bilieux" is not allied with yellow fever. (5) Hæmoglobinuric fever presents some points of resemblance to yellow fever, though there are many features of differentiation; it is unfortunate that recent inquiry has not given us a bacterium as the etiological factor in yellow fever, for mere clinical evidence is wholly unsatisfactory.

Deutsche medicinische Wochenschrift, September 4, 1902.

Experimental Cancer Investigations.—E. V. Leyden and F. Blumenthal communicate the results of some preliminary work which they have conducted with respect to the etiology and treatment of carcinoma. All their attempts to transfer by inoculation human cancers to animals were unsuccessful. Cancerous rats and mice could not be kept alive for a sufficiently long time to enable experimentation upon these animals to prove satisfactory. Dogs were selected as the most suitable animals, and transference of carcinomas from one animal to another was easily effected. Carcinomatous dogs were treated in two ways: (1) By the inoculation of the serum of rabbits which had been previously injected with carcinomatous tissue of dogs. (2) By the inoculation of a fluid which had been obtained by extractions from carcinomatous tissue of dogs. Both of these methods of treatment were successful, in that the tumors were decreased in size, softened, and in some instances entirely broken down thereby. Microscopical examination showed that the tumors were undergoing a fatty degeneration, as the result of the inoculations. The principals of the latter method were applied to the treatment of human carcinoma. Three patients were inoculated with a fluid obtained by extraction from human carcinomas. All three were inoperable cases, and all but one were far advanced in age. All of the patients died. Upon autopsy no metastases were found, and the tumors were in a state of fatty degeneration. These experiments, while not in any way conclusive, give good reason to expect that much advance in the treatment of carcinoma will be obtained by further study along these lines.

Injurious Effects Produced by the Subcutaneous Injection of Tavel's Salt-Soda Solution.—Baisch is very outspoken concerning the injurious effects produced by the subcutaneous injection of Tavel's salt-soda solution. Baisch reports six cases in which it was used. In all of the cases extensive gangrene and necrosis was produced. One of the patients died as a direct result of the gangrene. Even under the most favorable circumstances the lesions caused by the necrosis showed little inclination to heal, and in several instances transplantation was necessary. In every instance rigid antiseptic precautions were used at the time of injection, and the fluid used was sterile, so that the unfavorable results could not be attributed to neglect in these matters. In order to ascertain to what the injurious effects were to be attributed, animal experimentation was undertaken. Guinea-pigs and rabbits were inoculated subcutaneously with physiological salt solution and with Tavel's solution under rigid antisepsis. The animals which were thus treated with the physiological salt solution never showed any ill effects therefrom, while those upon which Tavel's solution was used regularly showed a necrosis and gangrene. Other animals were subcutaneously injected with a $2\frac{1}{2}$ per cent. soda solution (calcinated soda was used). These animals likewise developed an extensive gangrene and necrosis whenever any considerable amount of the solution was used. Intravenous and intraperitoneal inoculations of Tavel's solution and the pure soda solution did not produce any unfavorable results. From these experiments it is seen that the ill effects produced by the subcutaneous injection of Tavel's solution are due to the soda which this contains, since this causes a destruction of the cells of the subcutaneous connective tissue.

Berliner klinische Wochenschrift, September 8, 1902.

Herpes Laryngis Menstrualis.—Bettman describes a form of herpes which affects the larynx and occurs chiefly in connection with the menstrual epoch. The patient described was suffering from secondary syphilis, and had suffered from herpetic eruptions at various times on other portions of the body. The laryngeal affection appeared suddenly during a menstrual period. It was not accompanied by any general symptoms. There was a temporary loss of voice and some swelling and redness of the throat. Several herpetic spots appeared upon the face simultaneously. An examination of the larynx showed the presence of several typical herpetic lesions. The acute laryngeal symptoms were only of a few hours' duration but the lesions did not entirely disappear for several days. The patient was under occasional observation for a period of about two years thereafter. No laryngeal trouble was ever again noticed, but herpetic eruptions in other regions were almost a constant accompaniment of menstruation. They were never observed at any other time. The case was undoubtedly one of herpes menstrualis, and the single attack in which the larynx was affected may be described as herpes laryngis menstrualis, a name which has not hitherto appeared in medical nomenclature.

Hæmatology of a Case of Severe Lead Anæmia.—Alfred Wolff reports observations which are interesting as throwing some light upon the question of a vicarious myeloid action of the spleen. The patient died from the effects of a severe lead anæmia. Before death an examination of the blood showed the usual characteristics of such an anæmia, and in addition a leucocytosis of about 25,000. This leucocytosis was polymorphonuclear neutrophilic in character, these cells being present in 86 per cent. No myelocytes or abnormal cells were present. Post-mortem examination of the bone marrow showed a marked preponderance of non-granulated over granulated cells. Most of the non-granulated cells were of the type described previously by the author as lymphoid cells, which it is claimed become transformed into granulated polymorphonuclear cells. The find of these cells in the bone marrow in excessive numbers in this case would seem to bear out this view. The examination of the spleen revealed the presence of many neutrophilic and eosinophilic myelocytes, together with many nucleated red-blood cells. Very few nucleated red-blood cells were found in the bone marrow. In this case, therefore, the bone marrow had largely lost its blood-forming properties, and the spleen had taken on a vicarious myeloid action. The observations in this case are thus confirmatory of recently reported by Hirschfeld, who has described a myeloid action of the spleen in many cases of the infectious diseases.

Development of Hydrophobia Seven Months after Treatment with Pasteur's Protective Inoculation.—Theodor Kasparek and Karl Tenner report the case of a child seven years of age who was bitten on the hand by a rabid dog in September, 1900. Thirteen days thereafter protective inoculations were begun at the Pasteur Institute in Vienna, and were continued for a period of fifteen days. The child remained perfectly well until May, 1901, when it was seized with symptoms of hydrophobia and died in six days, under the clinical picture of the raging form of this disease. The medulla oblongata was removed at autopsy, and portions of it inoculated into two rabbits. Both of these animals died of hydrophobia—one of the raging and the other of the paralytic variety. The chief interest in the case lies in the very lengthy period of incubation. Very few cases have been recorded in which the disease developed as late as seven months after infection. The records show that after the use of the Pasteur treatment an incubative period of even two months is rare. It is also interesting to note that in this case the bite was on the hand. It has always been supposed that in bites of the upper extremity the period of incubation was short, corresponding to the short distance which the toxin had to traverse through the nerves to reach the brain. This case shows, however, that such is not always the case, and that hydrophobia following bites of the upper extremity may show an exceedingly long incubative period.

Münchener medicinische Wochenschrift, September 9, 1902.

A Giant Lipoma.—H. Pfeiffer observed in an eighty-four-year-old female a lipoma which weighed from twenty-eight to thirty pounds, and was eighty-five centimeters in circumference at its largest portion. The tumor was located upon the back, its peduncle originating in the lower cervical and upper dorsal regions. The patient carried the tumor about in a sling-like bandage, similarly as a soldier would carry his knapsack. Its surface showed superficial ulceration in several places. The growth was of thirty years' standing.

Treatment of Dysentery with Ipecacuanha.—Julius Strasburger reports two cases of amœbic dysentery which were treated successfully with ipecac after numerous other remedies had been used in vain. Both patients had contracted the disease in tropical countries, and had suffered therefrom at intervals for several months previous to coming under observation. The daily dose given was from one to two grams of powdered ipecac. This was combined with 10 drops of laudanum. The improvement following this treatment was astonishingly rapid. Recurrent attacks were not, however, prevented. The results could not be ascribed to the tr. opii, since this had been given alone and without benefit previous to the administration of the ipecac. The author regards this drug as a specific for amœbic dysentery, but has had no experience with it in the bacillary form.

Action of Atropine upon the Intestine.—Paul Ostermaier extols the use of atropine in the treatment of incarcerated hernia. Six cases of inguinal hernia are reported in which this drug was used hypodermically. The dose given was from one to two milligrams of atropine sulphate. Spontaneous reduction occurred in all the cases. In four cases only one dose was given. In one two injections were required and in another three were necessary. In these cases the doses were repeated at two-hour intervals. In all of the cases relief from pain almost immediately followed the initial injection and the general condition rapidly improved. It is probable that the mode of action of the atropine in this condition is varied. In the first place, intestinal peristalsis is increased. Furthermore, the blood vessels involved in the incarceration are contracted. Lastly, it is probable that the muscular structures surrounding the opening in the abdominal wall are made more lax. The author believes that this treatment should always be substituted for taxis. It should not, however, be used where herniotomy is required, as in this class of cases no time is to be lost in relieving the incaceration.

Uterine Rupture in the Early Months of Pregnancy.—Karl Kober reports a case in which an abortion was attempted in the second month of pregnancy. The cervix was forcibly dilated and the uterine contents extracted by the means of a sharp curette. Immediately following there occurred an alarming uterine hemorrhage, which was only controlled by means of a tampon. At the end of twenty-four hours the tampon was removed and hemorrhage immediately began anew. A fresh tampon was applied, which was removed in twenty-four hours, followed by a second recurrence of the hemorrhage. A similar repetition occurred on each of the three following days. Operative measures were deemed necessary. Upon examination a large rent was found just above the internal os. Douglas's cul-de-sac contained a large clot. The uterus was at once removed per vagina and recovery rapidly followed. Upon examining the amputated organ, two rents were discovered, the one mentioned above near the internal os, which was undoubtedly caused by the forced dilatation, and another in the region of the fundus, which was produced by the sharp curette used in evacuating the uterus at the time of the abortion. The lessons from this case are obvious. (1) Never use forced dilatation in producing abortion in the early months of pregnancy. (2) Never use a sharp curette in evacuating a uterus in a like condition.

French Journals.

Importance of Hygiene in the Treatment of Exophthalmic Goiter.—Raoul Leroy and Lucien Veslin report the case of a woman of thirty-nine years who was suffering from a typical attack of exophthalmic goiter. An operation had been advised, and, in great fear, the patient presented herself to the writers for advice. They enjoined the strictest hygienic life, consisting of a mixed diet, absolute avoidance of all spirituous drinks, and of all excitement and emotion, the observance of exercise without fatigue, of perfectly regular hours for sleeping, rising, and eating. After the exercise followed hydrotherapeutic treatment. Under the influence of this severe method of life, improvement began to take place in two months. She regained an almost normal condition in less than a year. The cure was perfect, and has lasted now for eighteen months.—*La Presse Médicale*, September 6, 1902.

The Comparative Digestibility of Plain Milk and Skimmed Milk. Gilbert and Chassevant have studied, experimentally, the duration of stomach digestion for plain and for skimmed milk. They have determined that: (1) Boiled skimmed milk stays in the stomach a shorter time than plain boiled milk, contrary to the hypothesis of Marckwald and in conformity with clinical observations. (2) It takes more than four hours and a half and less than five hours for boiled skimmed milk to be expelled from the stomach, and more than six hours and a half and less than seven hours for plain boiled milk. (3) It is the fatty part that stays in the stomach the longest time. Some of it remains at the end of six hours and a half, when almost all of the nitrogenous material has disappeared. The fatty part retards the digestion of the nitrogenous material about two hours. Plain milk stays in the stomach longer than boiled milk.—*Le Bulletin Médical de Quebec*, August, 1902.

Transmission of Tuberculosis by Milk and Meat.—John J. Repp concludes that: (1) Tuberculosis can be transmitted from one animal to another: *a*, experimentally by the inoculation of meat or by the juice of infected meat; *b*, by the ingestion of these meats; *c*, by the ingestion of the milk of tuberculous cows. This milk could produce tuberculosis in healthy animals, even if the diseased cow did not present specific mammitis. (2) The Koch bacillus of cattle is pathogenic for man. (3) The use of the milk and meat of tuberculous animals can be dangerous to man. As to the meat, the flesh of animals used for food, and notably that of cattle is not good, if the animal is tainted with tuberculosis which is extensive; it will be proper for food if the animal is only slightly diseased, especially if the meat has been cooked after elimination of the lesions. As to the milk: the use of milk of a cow with tuberculous mammitis always exposes the subject to the infection, unless the milk has been carefully sterilized. The milk of a tuberculous animal without mammary lesions may be dangerous. As it is difficult to determine those cases in which it is dangerous, it is best not to use the milk of any tuberculous animal.—*Le Mouvement Hygiénique*, August, 1902.

Treatment of Hypertrophy of the Prostate by Light.—M. G. Gautier states that light gives curious results in the treatment of hypertrophy of the prostate. Negative phototherapy and positive phototherapy may be applied, the two associated, or not, with the Röntgen rays. In the spectrum, there exist the chemical rays, comprised in the blue, violet, and ultra-violet (negative), and the rays comprised in the red and infra-red (positive). The red calorific rays, thanks to the special lamps, of two amperes with 110 volts, directed on the perineum and inferior abdominal region, exercise a beneficial action on the retention of urine and the hypertrophy of the prostate. The same lamps, enveloped by a blue globe, cause anamelioration of the painful symptoms. The double benefit, diminution of the retention of urine, and amelioration of the spasmodic pain, added to the improvement of the general condition of the patient, is obtained in from four to eight seances. In three cases the application of the Röntgen rays alone to the perineum was very efficacious, but the results were less rapid. The advantages of the method for the cure of hypertrophy of the prostate are: Increase of vesical contractility; rapid disinfection of the bladder by an aseptic treatment; more abundant evacuations; amelioration of the pain of micturition. In the young patient it is a treatment worthy of attention. In the old patient it is a palliative method, but of incontestable value in every case in which there are no infections. This treatment must be used for a longer time before final conclusions can be drawn.—*Le Progrès Médical*, September 6, 1902.

University of Pennsylvania Medical Bulletin, August-September, 1902.

Epithelioma of the Axillary Glands. Presenting the Clinical Features of Tuberculosis.—I. Valentine Levi reports a case in which the history, the clinical symptoms, and examination all led to a diagnosis of tuberculous osteomyelitis of the humerus with glandular involvement. Operation was advised and performed. An examination of the tissues from the operation showed epithelioma, with no evidence of a tuberculous process.

Diagnosis by Means of the Serum of the Blood.—Joseph Sailer states that at present the following reactions appear to be definitely established: (1) Those between microorganisms producing infections and the serum of the infected animals. (2) Those between the red blood corpuscles of one species of animal and the serum of any other species of animal into which the former have been injected. (3) Those between bacterial cultures and red blood cells. (4) Between normal blood serum and bacteria. (5) Between normal or pathologically altered blood serum of certain animals and the blood corpuscles of the same or other species. (6) Between cells derived from various organs of one species of animal and the serum of an animal of another species into which an emulsion of these cells has been injected. (7) The reactions that take place in the body when active sera, either derived from inoculated animals or from normal animals of certain species, are injected into animals, experimentally.

The Influence of Alcoholic Intoxication upon Certain Factors Concerned in the Phenomenon of Hæmolysis.—A. C. Abbott and D. H. Bergey draw the following conclusions from the results of their experimentation: (1) The daily administration of alcohol per os to rabbits brings about a reaction in their circulating blood of the hæmolytic complement. (2) Slight alterations in the normal alkalinity of the blood serum have no demonstrable influence upon the hæmolytic complement of the blood of alcoholized rabbits. (3) The diminished reacting power of the blood of alcoholized rabbits is not due to the presence of small amounts of alcohol as such in the blood. (4) The administration of alcohol to rabbits induces not only a marked reduction in the complement content of their blood, but may cause, at the same time, a reduction in the specific hæmolytic receptor in the blood of rabbits artificially immunized against an alien blood (5) The diminished complement content of the blood of alcoholized rabbits renders the animal more susceptible to the toxic action by an alien blood.

The Present State of Our Kowledge of Diabetes Mellitus.—James Tyson says that there appears to be. (1) An alimentary glycosuria due to an imperfect assimilation of carbohydrates into fat and proteid in the intestinal villi, as a consequence of which it passes over into the portal circulation in larger quantity than can be converted into glycogen by the liver. (2) A glycosuria due to the overproduction of glucose out of hepatic glycogen. (3) A glycosuria due to the fact that through vasomotor influence the glucose passes through the liver too rapidly to permit its conversion into glycogen. (4) A glycosuria due to defective oxidation of glucose. (6) Glycosuria arising from the disruption of proteid, witn the liberation of glucose. The tendency of modern thought is toward defective oxidation as the cause of abnormal glycæmia and glycosuria. The author enters fully into the question of treatment of the condition and endorses Dr. Richardson's method of daily bathing with warm water, sun baths, soda baths twice a week, flannel clothing, and walking exercise, in spite of the lassitude and weakness which makes this mode of treatment particularly irksome.

American Journal of the Medical Sciences, September, 1902.

Entrance of Air into the Veins, and Its Treatment.—Malcolm Goodridge sums up his paper as follows: (1) Entrance of air into the veins, even in small amounts, is to be dreaded, as it may result in death. (2) Death is due to gaseous distention of the right heart or to air emboli in the coronary vessels, and not to primary respiratory paralysis. (3) We may expect combined treatment by aspiration and infusion to be followed by good results. He believes the statement "that large quantities of air may be introduced into the veins without unfavorable result" to be pernicious teaching and not supported by fact.

Post-Operative Non-Septic Leucocytosis and Other Blood Conditions.—Herbert Maxon King concludes that: (1) An increase of from 5,000 to 10,000 leucocytes per cubic millimeter following operation in from six to thirty-six or even forty-eight hours is a normal post-operative condition, provided it be not sustained. (2) Probably the maximum leucocytosis in the majority of cases occurs within the first twelve hours after operation, and is very transient. (3) The leucocytosis in the normal reparative process bears but slight relation to the pulse and temperature. (4) A post-operative leucocytosis of 10,000 or more above the individual normal sustained for more than a few hours may be looked upon with suspicion. (5) The apparent increase in number of erythrocytes following operation is not caused by an actual increase of red cells in the circulating blood.

Benign Cystic Epithelioma; Report of Two Cases Presenting Unusual Features.—M. B. Hartzell describes these cases. The first patient was a woman, aged about eighty years. She had a rounded, dollar-sized patch of nodules, made up of several smaller groups, arranged in an irregular circinate manner around scar-like areas, on the right-side of the forehead over the frontal eminence. The nodules were mostly confluent, of the size of a hempseed, firm, translucent, bluish-white, with a small blue-black dot in the center of each. Near the center of the patch was an oblong, superficial ulcer, covered with a thin crust. The lesion had lasted six or seven years. There were rather the addition of new nodules than the enlargement of the old ones, which remained stationary after reaching a certain size. There was no pain or marked subjective symptom of any kind. No similar lesion was in any other part of the body. The second patient was a woman of thirty eight years. She had six or seven dime- to half-dollar-sized oval and irregularly-shaped, sharply-limited patches, consisting of central areas of scar-tissue and atrophied skin, surrounded by a bead-like border of pinkish and yellowish large pin-head to split-pea-sized nodules, on the upper back and chest. The nodules were firm and slightly translucent The affection had lasted four or five years, and was not attended by any subjective symptoms The writer then gives a careful and detailed microscopical description of the lesions. He also gives a number of cases reported by different authorities, and states that he believes that they represent three affections presenting lesions which can only be differentiated under the microscope, but which are distinct in their nature and origin: Benign cystic epithelioma, in which the lesions are usually on the face, and have their origin in the basal layer of the epidermis and the external root-sheath of the hair, cyst-adenoma, in which the eruption occurs upon the trunk the tumors starting in the sweat-gland apparatus, hæmangio-endothelioma, which appears on the trunk, and originates in a proliferation of the endothelium of the blood vessels.

A Report of Ninety-two Cases of Thermic Fever Treated at the Pennsylvania Hospital in the Summer of 1901.—Morris J. Lewis and Frederick A. Packard base their report on ninety-two cases of thermic fever, which occurred in their service during the extremely hot weather of July, 1901. It includes all those cases showing a temperature of 100° F. and over, upon admission The time of day at which the greatest number were received was from eleven o'clock in the morning until five o'clock at night, the maximum being from three until five o'clock, showing the effects of fatigue and long exposure. Thirty-one of the cases were females and sixty were males. This is an unusually large proportion of women. The extremes of age were seven months and over 70 years. The average was about thirty-seven years. Six patients were negroes, showing the immunity of this race. The greater number were natives of the United States. Convulsions were noted in fourteen cases, and were generally severe Those patients with a temperature of 106° F. and over were generally unconscious when brought to the hospital. The previous habits of the patients seemed to have an important influence on the result. In the mild cases no alcoholic history was obtained. As to treatment, the writers do not advise bleeding as a routine measure. In certain cases in which the fall in temperature was not accompanied by a corresponding decrease in the other grave symptoms it proved beneficial. In some cases in which the other symptoms do not improve, as the temperature is reduced by rubbing with ice, bleeding from the median basilic vein causes the pulse, respiration, and color of the skin to improve. It seems difficult to estimate the value of the introduction of normal saline solution, but there was no evidence of any harmful action and usually the patient's condition was improved by either this or bleeding. As to the sequelæ, there was one case of jaundice coming on three days after onset. The writers believe that the introduction of normal saline solution in large quantities into the blood has a beneficial result.

Report of Three Cases of Creeping Larvæ in the Human Skin (Hyponomoderma, Kaposi).—Arthur Van Harlingen declares that the number and variety of animal parasites of the human skin are probably far greater than has been generally supposed. Thus, these cases are often wrongly diagnosed. The first case that he reports was a child of four years. It had had an eruption of the foot of three or four weeks' duration. The eruption had originated, according to the history, on the heel, in the form of a small water blister, which had gradually extended on one side, while healing on the other, following a serpiginous course, and terminating in a spiral in the skin over the inner malleolus. The lesion looked like a line of small vesicles, resembling, in a magnified degree, the furrow made by the itch insect. It was very itchy. The patient was ordered to have the skin well rubbed with an ointment of sapo viridis and tar along the line of the disease. At the end of four weeks not a trace remained. The second patient was a boy, aged five years. There was an eruption on the sole of the foot, consisting of a flat, red, narrow line, curving from one side of the foot to the other, and resembling the edge of a circinate erythema. There was considerable itching. Later the lesion appeared like a whip-cord under the skin, and it was painful. It was cut down upon, but no living organism could be found. But from that time the red line began to disappear and, finally, entirely faded away. Possibly the incision6exposed the parasite and it was washed away by the blood. The third case was that of an employee in the Custom House. The eruption in this case was on the hand, and followed a serpentine course. The writer cut down on the supposed worm at various points, but without finding it. He then prescribed asafœtida, after which the red cord faded away. There was a slight trace of irritation at the end of the lesion, but the patient felt sure that the parasite was dead. The writer has not seen him since. The writer believes these cases to be the first ones of the kind to be reported in this country.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

The Fourteenth Annual Meeting, Held in Washington, D. C., September 16, 17, and 18, 1902.

The association met in the convention hall of the Raleigh Hotel, under the Presidency of Dr. Edwin Ricketts of Cincinnati, Ohio.

An address of welcome was delivered by Surgeon-General Geo. M. Sternberg (retired) of Washington, which was responded to by the President.

Pelvic Disease in the Young and Unmarried.—Dr. C. L. Bonifield of Cincinnati, Ohio, read a paper with this title. He dealt only with gynecological diseases which occurred in women not subjected to sexual intercourse. Physicians were now more frequently consulted about such troubles than formerly, but this was probably because the modern woman bore discomfort less well than her ancestors did, rather than that there was an increase in the number of patients suffering from such disorders. Disorders of menstruation, undeveloped uterus, tuberculous disease of appendages, and acute displacements were the most common pelvic affections in such patients. When menstruation did not make its appearance at the age it was to be expected, a thorough investigation of the general condition of the patient was indicated, and her health should be made as nearly perfect as possible. A local examination was not required unless there were severe local symptoms. The same was true of amenorrhea occurring after menstruation had been established. The possibility of pregnancy was always to be borne in mind. Dysmenorrhea might be of constitutional or local origin. Local treatment was not required in the first variety, and the endometritis which caused a majority of the latter cases could often be relieved by hygienic and medicinal treatment. Menorrhagia was often caused by a depraved state of the blood, or an interference with its circulation by disease of the heart, liver, or kidneys. The uterus, whose development had been arrested at the time of puberty, was the most important type of undeveloped uterus. It was generally sharply anteflexed, but occasionally retroflexed, and the cervix was long and narrow, the body dilated. Dysmenorrhea was a prominent symptom. Thorough dilatation, curettage and tight packing, repeated one or more times, if necessary, constituted the best treatment.

Tuberculosis of the pelvic peritoneum was often mistaken for typhoid fever or appendicitis. When tuberculous peritonitis began in the uterine appendages, these should be removed by abdominal section.

Acute prolapse or retroversion of the uterus was found as a result of a fall or heavy lifting in young women of lax fiber.

Young unmarried women were best examined under anæsthesia, and, when possible, the treatment of their local disease should be operative.

Removal of the Gall-bladder Through the Lumbar Incision.—Dr. Walter P. Manton of Detroit, Mich., read this paper. He reported a case of removal of the gall-bladder through the lumbar incision. The patient, aged thirty-eight years, the mother of five children, with two abortions, had never been robust, but was able to attend to her domestic duties. She had suffered from a number of gastric attacks, but there had been an entire absence of symptoms pointing to the disease of the biliary tract. Examination showed the left kidney to be loose, while the right kidney appeared to be double its normal size, displaced downward and inward, and with certain projections which led to the diagnosis of nephroptosis, with probably cystic metamorphosis of the kidney. At the operation, through the nephropexy incision, the fatty capsule of the kidney was found to be embedded in a mass of adhesions, which had given rise to the appearance of the enlargement. The kidney, which was normal in size and structure, was delivered onto the back and placed astride the wound. Below the kidney pouch a distended gall-bladder, containing fluid and nineteen gall-stones the size of hazel-nuts were found surrounded by adhesions. This was enucleated, tied off at the cystic-duct, and removed. The fluid contents of the sac contained a bacillus having the morphology and staining qualities of the colon bacillus, and a long, large rod, which stained violet by Gram's method, but no staphylococci or streptococci. The kidney capsule was split and peeled off to the lateral line, fixation sutures were introduced, and the organ was returned to its place. A strip of gauze for drainage was carried from the upper angle of the external wound to the stump of the cystic-duct. The patient made a good recovery.

It was impossible to state whether the condition was a congenital anomaly or the result of the walling off of the gall-bladder by adhesions. The operation was entirely extraperitoneal. This was the first recorded instance of extirpation of the gall-bladder through the lumbar incision. Manton believed that, on account of the anatomical position of the gall-bladder in uncomplicated disorders of the biliary tract, the anterior abdominal incision was the one of choice, but that when nephroptosis or a morbid condition of the kidney existed demanding operative treatment, together with enlargement of the gall-bladder from stones or fluid accumulation, the lumbar route offered certain advantages. He paid tribute to Edebohls as the pioneer whose work had opened up this previously uncultivated field of surgery.

Drainage in Abdominal and Pelvic Surgery. Dr. Joseph Price of Philadelphia, Pa., in a paper on this subject, stated that the more progressive and successful specialist doing painstaking operations in every detail, where filth and complications, or adhesions, were found to exist, practised most extensive sponge packing or drainage. The modern operator did the same by his gauze pack or the dry operation. A number of operators, doing fairly good work by the suprapubic route, condemned or partially rejected drainage. He said some of them never learned and never would learn how to handle drainage well. After abandoning the suprapubic route, these men were placed in the uncomfortable position of admitting that drainage did what they had refused to do by suprapubic surgery. Nothing had pleased the speaker more in the last few years than a knowledge of the fact that the young school of surgeons used drainage with great success and skill in spite of the fact that these young men had been under the instruction of men about the country and in the hospitals who condemned it. About all the reported operations were coming from operators opposing drainage or practising it only when they were compelled to do so.

The Vaginal Route for Operations upon the Uterus and Appendages.—Dr. J. H. Branham of Baltimore, Md., stated that the most common condition threatening the life of gynecological patients, caused by gonorrhœa, abortion, tuberculosis, and other conditions not always discernible, and often requiring prompt action to save life, was pelvic inflammation. Here the vaginal method of treatment made its best showing. He had operated on more than one hundred cases by this method, with but three deaths. He concludes that vaginal drainage was the natural method. It was far more effective and safer. Extensive pelvic inflammation, associated with pus formation, rapidly walled off the general peritoneum. This wall should not be broken through, and could not be interfered with without danger of general peritonitis. Opening through the vagina was associated with a minimum amount of shock and hemorrhage, and was thus indicated in extreme cases associated with severe toxic symptoms.

Ice Following Abdominal Section.—Dr. F. F. Simpson of Pittsburgh, Pa., advocated the local use of ice for the relief of pain, to prevent or control peritonitis, and to limit the morbid products following operation. These things, he thought, were due almost wholly to inflammation, which was very slight and purely traumatic, in the vast majority of cases, but might be bacterial in a few others and in unclean cases. This use of ice he began after observing its effects in several hundred cases of pelvic peritonitis of all grades prior to operation. In this connection he said: "After having seen many grave cases of this kind yield so favorably to this measure, and having seen a few of them die later from peritonitis following an abdominal section, which removed the bulk of filth, leaving but little behind in a fairly clean cavity, it seemed to me that with the same infecting organisms active in large numbers before operation, and in small numbers after operation, we might expect like results if the same treatment were employed in the two classes of cases. And, further, that by beginning the use of ice before peritonitis had actually developed, we might succeed in preventing that condition."

He further asserted that the use of ice after operation had been highly satisfactory in some hundreds of cases during the last four years.

Regarding theoretical objections, he said that they disappeared as physicians became familiar with the use of ice. In his experience, no injury to the skin had followed its use, the healing of wounds had not been retarded by it, and no depression of the general system had been noticed.

He attributed the beneficial effect of cold to its direct and deep penetration. This opinion was based upon the known effects of cold on surface inflammation; upon the satisfactory results he had gotten at the bedside; upon the observations of Boklikoff, who showed that cold actually penetrated deeply into the human cavities and tissues; and upon his own experiments on dogs, which showed that by the local use of ice there could be produced within the abdominal cavity and without detriment to life or tissue, such a degree of cold as would retard the growth of pathogenic bacteria and contract the blood lymph channels, thus depleting the hyperæmic areas and checking serous weeping into the peritoneal cavity.

He related several cases in substantiation of his views, and gave in detail his experiments on dogs.

Two Fatal Cases of Tetanus, Following Abdominal Section, Due to Infected Ligatures; with a Plea for the Angiotribe in Abdominal Surgery.—The author of this paper was Dr. Walter B. Dorsett of St. Louis, Mo. Both cases, which were detailed at length, were in women who had undergone ventrofixation of the uterus. The choice of the operation was made on account of adhesions of the uterus to the surrounding tissues, due to previous inflammatory conditions. The material used for fastening the uterus to the anterior abdominal wall was kangaroo tendon, a little above the average size.

Speaking of the angiotribe, he had used it successfully twenty-five times, as follows: abdominal hysterectomy, ten times; pus tubes, five times; hemorrhoids, once; extrauterine pregnancy, four times; dermoid cyst, once; ovariotomy, three times, and once in a case of vaginal hysterectomy.

His observations were that (1) patients upon whom it had been tried suffered less post-operative pain; (2) No adhesions to stumps had followed its application; (3) No secondary hemorrhage had followed its application; (4) It can be applied, when two instruments were used, alternately by the operator and the assistant without the fear that is incident to the slipping of a ligature knot, and in less time.

Some Problems in Exploratory Laparotomy.—Dr. Walter B. Chase of Brooklyn, N. Y., said that the diversities and uncertainties of physical signs and rational symptoms related to certain diseases of the contents of the peritoneal cavity, being insufficient for purposes of diagnosis, surgical intervention might be necessary to determine the exact state of affairs. Exploratory abdominal section for diagnostic purposes was of comparatively recent date. Its growth had been progressive, but the limitations as yet were not clearly formulated. Training and skill in diagnosis, judgment, having in it the planning of soberness and daring coupled with years of apprenticeship, would guide one to safe conclusions. In chronic cases there might be ample time for study and analysis, with comparison of the progress and fluctuation of symptoms, which would furnish valuable data for forming deliberate judgment. Surgical intervention was looked upon much more favorably by a discriminating public to-day than formerly, so that the suggestion by the surgeon that an operation was required found a more ready response by the patient or the patient's friends. The surgeon, however, owed a duty to the public which had in many instances been neglected, namely, to make it clear to the patient or the friends, and thus to the public, that there was such a limitation to our knowledge that we were perforce required to explore for causes. He believed that a frank confession of this truth would, with right-thinking people, strengthen the position of the operator. There was a widespread belief among the laity, not founded on fact, that deaths following laparotomies and other major operations were due to the operations *per se*, and not to the causes for which the operation was done. The sooner these false beliefs were eradicated the better it would be both for the profession and the public. The duty of correction of this erroneous statement lay with the medical profession.

Ruptured Pus Tubes.—Dr. Charles Greene Cumston of Boston, Mass., said there were two methods of dealing with pus tubes, one of which was posterior colpotomy, followed by incision and drainage of the sac, while the second was to remove the tube, and if the condition was bilateral to do a total hysterectomy. Naturally, the easiest and least dangerous method was drainage of the perforated pyosalpinx through the vagina. The vagina was incised, and then the pyosalpinx and the walls of the pus tube might be united to the vaginal wall by means of forceps, which were allowed to remain in place for one or two days until union had taken place. In doing this operation in two stages the vaginal walls were first incised, and the sac was united to the borders of the vaginal incision, and after union took place the pus tube was opened. In both instances the cavity should be thoroughly irrigated with salt solution and large drainage tubes employed. The proper treatment, however, for perforated pus tubes was abdominal incision, whether perforation had taken place in the general peritoneal cavity or into the intestine, bladder, or vagina. The extirpation of perforated pyosalpinx was particularly urgent in those cases in which drainage by posterior colpotomy had been unsuccessful, and also when one was dealing with a tuberculous lesion of the tubes. He did not favor vaginal hysterectomy in cases of perforated pus tubes, although he believed that when the sac had burst into the bladder the vaginal route might be indicated under certain circumstances.

Treatment of Pelvic Abscess.—Dr. Herman E. Hayd of Buffalo, N. Y., said there was a class of cases in which vaginal incision and drainage, supplemented by curettage, when indicated, should be first employed to get rid of the free pus, and then later an abdominal section should be done to relieve the patient of her suffering, when the danger and risks associated with such an undertaking were reduced to a minimum. A large collection of pus, low down in the pelvis, in a moribund woman should be evacuated through the vagina, and nothing more undertaken unless some grave complication set in. He had reference now to strong women who were suffering from acute active streptococcic infection, who had a high temperature, with great pain and tenderness, who were in splendid physical condition and, under ordinary circumstances, ready to submit to capital operations, and in whom there could be felt an acutely tender mass low down in the pelvis on one or both sides, and even filling up the cul-de-sac and in whom one was positive that there existed pus, which was easily determined by an aspirating needle passed through the vault of the vagina. In this class he strongly recommended early vaginal incision for the purpose of draining off all the free pus, and, if necessary, to extend the incision to one or both sides and evacuate tubal and ovarian abscesses, if easily reached. This procedure was without danger, and, instead of increasing the difficulties of future operations, they were very much simplified. The size of the mass would diminish; the immediate dangers of rupture into the bowel and bladder or peritoneum, were lessened; the pain and constitutional symptoms subsided, the pus organisms were lessened in their virulency, and the whole clinical picture of the case improved. Several interesting cases were cited in which the author had practised this method with success.

The Importance of an Apprenticeship in Operative Gynecology.—Dr. GURNEY WILLIAMS of Philadelphia, Pa., read a paper with this title, in which he said that the modern apprenticeship differed materially from that of a quarter of a century or more ago, when the specialty was being developed by men with large and varied professional and surgical experience. Again, the nature of the work in those days differed greatly from that of the present. Hospitals, now so common in every State and city, were not giving their resident physicians the practical education or using the vast amount of material at their command for that purpose. He spoke from experience in this matter, for, after serving in two large hospitals thirty-six months, it was necessary for him to go elsewhere for practical instruction and the apprenticeship desired. All hospitals, he contended, should be practical schools for the residents and the visiting medical and surgical staffs.

In considering the treatment of pus tubes, he said that dilatation, curettement, and prolonged drainage of the uterine canal were unsurgical procedures. He urged more radical operative measures, and said that vaginal incision and drainage was a temporary makeshift; that sooner or later 25 per cent. of the patients would return for a more radical operation; namely, abdominal section. So much had been said about the simplicity of puncture methods and drainage by the vaginal route, with speedy relief and recovery, that he wished to state that aside from the mortality, which was not small, the number of invalids leaving hospitals was very large. They returned to the same or other institutions for reincision or for abdominal section, and when one, who did such work, was thoroughly familiar with the postoperative conditions of both classes of cases, he was convinced by his every-day experience of the results and recoveries following the suprapubic method of clean extirpation. The mortality from this operative procedure was smaller, and the recoveries more pleasing than from any other measure, ancient or modern, now practised!

Technique of Bi-inguinal Cœliotomy for Complicated Aseptic Retroversions of the Uterus.—Dr. A. GOLDSPOHN of Chicago gave a résumé of the rationale and technique of Bi-inguinal cœliotomy for complicated aseptic retroversions of the uterus, and made a further report of its remote results. The argument he advanced was that (1) Surgical treatment could be consistently recommended for this disorder only if it was not merely innocent of harmful effects to subsequent gestation and labor, but if its good results were also not frustrated by subsequent childbirth. (2) Most of the operations in vogue did not meet this more ideal requirement, nor had most of their sponsors aimed so high. (3) The round ligaments of the uterus were the only truly serviceable structures to deal with to get such results, because they alone, as a part of the uterus, underwent both evolution and involution with it during and after gestation. (4) The route by which to gain their serviceability best was by the inguinal canals. (5) With a proper technique, the lateral inguinal rings provided ample access for the intrapelvic work in complicated but aseptic cases, without cutting and without hernia following. (6) A table showing later results of about thirty-five new examined cases, in addition to seventy-two cases previously reported, with no hernia in any of them. (7) In all known cases of subsequent childbirth, the women retained their uteri, etc., in pronounced anteversion and with good involution.

The Irrational Starvation Treatment of Appendicitis.—Dr. JOHN B. DEAVER of Philadelphia discussed this subject. The author's experience of ninety-eight cases for the past two and a half months had furnished a lesson from which objections to the rest or starvation treatment were drawn. The particulars of these cases were detailed. The lessons drawn were that an early operation, preferably in the stage of appendiceal colic, was the only rational procedure, and was the only treatment which would reduce the mortality in acute appendicitis to insignificant figures; that the so-called rest treatment of appendicitis failed to check peritoneal inflammation, and would, in the majority of cases, harm the patient. The statistics presented in the paper bore out the above statements to the letter. Cases brought to the operating table several days after the onset of the disease, where the starvation treatment had been carried out, and a local abscess or a mass of exudate and adhesions found, had by no means convinced him that those patients would not have been better off by early operation. To attempt to foretell what the intraperitoneal condition was, or what it would be a few days or weeks later, was assuming a graver responsibility than was justifiable. Such a prediction was never made by those whose experience with the disease would justify such a confidence. He was willing to grant that operation in the presence of an acutely inflamed general peritonitis was attended by great risk of life, and, therefore, it was often wise to defer operation in the hope that the inflammatory process would become localized. This was often his practice; but he denied that the starvation plan of treatment promised more in such cases than the mere common practice of abstaining absolutely from giving opium, keeping the bowels freely open by solid cathartics, or, as some physicians preferred, a hydragogue cathartic, which was both antiseptic and germicidal, giving nourishment by the rectum, when the stomach was tolerant, and using ice or heat locally in the shape of poultices or hot turpentine stupes.

Dr. JOSEPH PRICE of Philadelphia discussed the surgical relations which the appendix bore to pelvic suppuration and operative complications.

Our Shortcomings: Let Us Reason Together.—This was the title of the presidential address, which was delivered by Dr. EDWIN RICKETTS of Cincinnati, O. He called attention to the growth of the association, and spoke of the thirteen volumes of transactions which it had issued under its able secretary, also to more than one thousand pages of discussions, which stood as the result of thirteen years' work toward erecting a monument that was to be an honor of their unselfish efforts to true special work.

Speaking of the general practitioner, he said he was the backbone of medicine. It should not be otherwise. With just and coequal considerate relations the best interests of the physician and specialist were not to be severed. With changed relations toward the general practitioner complications were sure to arise. Abdominal surgery in the hands of general operators was accompanied with a higher mortality than was that done by special workers.

Reasons were advanced why the physician and all those engaged in the practice of specialties should enter the political arena. It would teach them what organization was, what and how power can be wielded for good. It would result in pronounced efforts for the organization of the medical profession, which, in due time, was to command respectful consideration from the national, State and county governments. Such would make a free and independent profession.

The true relationship of the neurologist as bearing on special work should be better appreciated. The neurologist should be called in consultation oftener, and he, in turn, should consult with the gynecic and abdominal surgeon before sending any of his patients to an institution for partial or permanent detention.

He urged the appointment of a national secretary of medicine, which, he believed, would put medicine on its highest and broadest plane. This would mean dignity, higher regard, influence, and an equitable financial remuneration.

Some Cases of Appendicitis and the Lessons They Teach.—Dr Miles F. Porter of Fort Wayne, Ind., reported the following cases:

Case I.—Chronic appendicitis of eleven years' duration. Operation; abscess behind the cæcum; small stump of appendix attached to the cæcum. Complete relief for six months, then return of symptoms, which were relieved by spontaneous opening of abscess. Return of symptoms, probably due to the distal end of the appendix or a fecal concretion left behind.

Case II.—Simple drainage operation done eleven months before, followed by frequent recurrences of pain, etc., relieved by spontaneous opening of sinus. Operation revealed a large fecal concretion and distal end of appendix free in center of abscess. Detached appendices or fecal concretions should be searched for in chronic cases, and drainage kept up for some time in case neither is found.

Case III.—The only tender point was discovered between the bladder and rectum by rectal examination, although prior to this symptoms were typical of appendicitis. Operation revealed a detached necrotic appendix enclosed in adhesions at this point. Microscope was necessary to determine the nature of the necrotic tissue.

Case IV.—Emphasized the remote dangers of delay in operating. First operation consisted of simple drainage of large pus cavity; two weeks later a second cavity in the left iliac region was drained; recovery well established, when bowel obstruction necessitated a third operation, and bowel had to be opened to allow replacement in abdomen. Five years later a fourth operation was necessary for bowel obstruction. Recovery; good health three years since last operation.

Case V.—Case of appendiceal colic due to seed of unknown kind. Tenderness circumscribed. Pain and tenderness out of proportion to the constitutional symptoms. Appendicectomy. Complete relief. Appendix not inflamed, but mucosa injured in several places by sharp corners of seed.

Case VI.—Complete occlusion of lumen of appendix. Some adhesions. No sign of present inflammation; but history of possible previous attacks. Appendicectomy incidental to diagnostic cœliotomy. Occlusion probably due to inflammation, but may have been lack of development.

Case VII.—Nothing unusual in this case, save that the tumor, composed of a mass of omentum enclosing inflamed appendix, was spherical and freely movable; could be pushed to left of middle line. Danger of mistaking similar case, if chronic, for tumor. Similar case thought at first to be one of malignant tumor related to writer by Dr. A. J. Ochsner.

Case VIII.—Girl, aged eleven years. Three previous attacks. Came on suddenly and disappeared in the same way. No tenderness after pain was gone. Small tumor, exquisitely tender, just above Poupart's ligament. Diagnosis, appendicitis. Operation proved case to be one of ovarian cyst with twisted pedicle and commencing gangrene.

Case IX.—Cancer of ileocæcal valve mistaken by several, including author, for appendicitis. Relative absence of tenderness, as compared with pain, together with anæmia and loss of flesh, which were out of proportion to the inflammatory symptoms, would lead in another case to a correct diagnosis.

Case X.—First attack; symptoms mild; appendicectomy. At the site of the appendix there was a small retention cyst of inflammatory origin with a very thick covering.

Case XI.—First attack; vomiting; tympany, etc., denoting severe and spreading infection. Operated on at the end of forty-eight hours, when first seen. Appendix perforated and gangrenous; free, muddy fluid in abdomen; recovery. What would have been the result of starvation treatment in this case? Can any method corral germs already widespread and pen them up securely within a small space? Will any medicinal treatment secure with certainty circumscribed abscesses in all suppurative cases? Can any one foretell the result in a given progressive case with certainty? He believed that the case would have ended fatally had operation been delayed. The sooner a case of appendicitis, which was growing progressively worse, was operated on the better. No man could tell until he saw the pathological changes that had obtained.

Four Cases Illustrating the Difficulties of Diagnosing Appendicitis.—Dr William Wotkyns Seymour of Troy, N. Y., read a paper with this title. Case 1 had previously been operated upon for appendicular abscess. He found a suppurating solid tumor of the ovary. Temperature at the time of operation was 107°; pulse 180. recovery. Case 2 was a woman with contracted pelvis delivered of a dead child. Twelve days later there were symptoms of inflammation in the right iliac fossa, appendicular or tubal, the result of infection. Operation revealed a suppurating gangrenous fibroid of the right anterior uterine wall, which was enucleated, followed by recovery of the patient. Later he did cæsarean section on this patient; mother and child well seven weeks after operation. In Case 3 he was summoned to a case of appendicitis some fourteen miles distant in the country. His diagnosis was ovarian cyst with twisted pedicle. The mass had increased twofold since his previous visit to the attendant. Removal of the cyst was followed by recovery of the patient. Case 4: woman, single, aged about twenty-two years; pains and intense tenderness in appendicular region; began with joint pains. Examination of lungs showed bronchial breathing at left base; the next day diffuse bronchial breathing over both lungs; appendicular symptoms less marked; toxæmia of some sort; no appendicitis.

Intrauterine Fibroids Complicating Pregnancy, and Retained Placenta Associated with Intrauterine Fibroids Complicating Pregnancy.—Dr. M. A. Tate of Cincinnati, O., had collected thirty-nine cases from the literature, and reported two which had occurred in his own practice. Analyzing these forty-one cases, the histories of which were not complete, he noted that in nine cases only were the names of reporters given, without any mention of history of the cases. In six cases the tumor became gangrenous; hemorrhage was a prominent symptom, in that it occurred in eighteen cases; three polyps were expelled spontaneously; seven polyps were removed; in three cases the polyp was not removed; in ten cases the labor was normal; in four cases labor was difficult, in two cases the child had to be destroyed; one was a case of turning, and the other a breech; in four cases the tumor was discovered before, in all of the rest after, labor; four cases were reported where labor set in before time; two were at the fifth, and two at the seventh, month.

The following were the complications reported: septicæmia, eight; measles, one; puerperal mania, one; retained placenta, four cases.

Treatment mentioned: cold applications, ergot, iodides, whiskey, vinegar cloths in the uterus, packing of uterus with gauze, and removal of tumor.

Causes of death: sepsis, three; hemorrhage, three; peritonitis, one; and collapse one, making in all eight cases. If all of the other cases, including the nine without histories, recovered, there would be thirty-three recoveries and eight deaths, a mortality of 19½ per cent.

Abdominal Section During Pregnancy.—Dr. J. Henry Carstens of Detroit, Mich., had had experience with the following complications of pregnancy: appendicitis, five cases; fibroids, four cases; hernia, one case; abdominal hysterectomy, one case; ovariotomy, three cases; vaginal hysterectomy, three cases; and miscellaneous three cases, or, altogether, twenty cases and five deaths, so that the mortality was 25 per cent. This included all his cases from many years back. He thought that to-day the mortality would be far less.

All acute diseases requiring prompt operation could be operated upon just as well as if pregnancy did not exist. Tumors that would interfere with labor should in all cases be operated upon, as there was far less danger attached to their removal during pregnancy than there was by nonintervention and letting the woman go to full term. He had seen most lamentable cases of the latter kind. Tumor above the brim of the pelvis, or which could be shoved above the brim of the pelvis, need not be interfered with; still, as a rule, all tumors took on a very rapid growth during pregnancy, and the increase in size might interfere with the various functions of life and then surgical intervention was required.

Deciduoma Malignum.—Dr. Lewis S. McMurtry of Louisville, Ky., read a paper on this subject and reported a case. Since Saenger, in 1888 and again in 1983, called attention to this form of malignant disease of the uterus, numerous cases had been reported in Europe and America. The diagnosis was not especially difficult, but great difficulty had obtained in establishing the exact pathogenesis and making a definite pathological classification of the disease. Saenger believed the growth originated in decidua cell and accordingly, gave it the name ever since in general use—deciduoma malignum. Gottschalk reported a case in 1894, and proposed the name "sarcoma chorio-cellulaire," believing the disease to be sarcoma springing from the stroma of the chorionic villi. In 1895 Marchand first published the result of his investigations of the disease, and supplemented this by additional researches published in 1898. His investigations were most thorough, and had done more to establish the true origin and pathology of the disease than those of any other investigator. He demonstrated the epithelial character of the growth, and asserted that it had its origin in the tissues composing the epithelial covering of the villi. According to Marchand's interpretation of the pathology, the tumor arises from the syncitium and Langhan's cells. Frankel and Gebhard had confirmed Marchand's observations, and his views had found general acceptance among German investigators This view of the pathology had also received general approval in Great Britain and America. It remained somewhat unsettled yet as to whether the tissues in which the growth originated were derived from fetal or maternal structures, or from both.

Clinically the disease presented a well-defined history. The disease appeared after abortion or labor, the tumor being situated upon the endometrium of the body of the uterus. Of 128 recorded cases, in forty per cent. the disease appeared after mole pregnancy. Hemorrhage was the first and most conspicuous symptom, and was not controlled by curettage. The discharge was usually offensive, especially in the advanced stage. The disease had a marked tendency to early metastasis; the lungs and vagina were the most common sites for metastatic deposits. The disease was so rapid in its course that the period from first symptoms until the death of the patient was only a few weeks or months. The only successful treatment was the early and complete extirpation of the uterus.

In the author's case the disease appeared in a woman of thirty-five immediately after abortion. Persistent hemorrhage and fetid discharge from the uterus prompted operative intervention. The uterus and its appendages were removed by abdominal hysterectomy, and the patient made a prompt recovery.

Perforating Ulcer of the Duodenum.—Dr. John B. Murphy of Chicago read this paper. He reviewed the salient points in the etiology, pathology, and diagnosis of duodenal ulcers, and considered especially the surgical treatment of perforations. He had collected from the literature nineteen additional cases, including one of his own, in which operations were performed for this complication. An analysis of these cases showed: Average age in the thirteen cases in which age was stated was thirty-five years. Of the nineteen cases, five were females and fourteen males. Of the twelve cases in which it was stated whether or not there were symptoms present previous to to perforation, in nine they were present previous to perforation; in three there were no prevous symptoms; in only five cases did the symptoms point to the stomach or duodenum; in six cases it was stated that the perforations were sutured; of these two died, three recovered. In one the result was not stated. In eight cases drainage only was used; of these seven died, and one recovered

Conclusions.—The diagnosis of perforating ulcer was difficult, or, better, practically impossible without an exploratory laparotomy. In many cases there was no evidence of duodenal disease previous to the perforation.

The most important physical sign, in addition to those of perforative peritonitis from perforations in other portions of the intestinal tract, was the flatness of the superficial piano percussion note in the right hypochondrium.

The leucocytosis in one case, the only one in which it was seen, was pronounced, showing an inflammatory condition, in contradistinction to the usual absence of it in intestinal obstruction and fat necrosis of the pancreas. Leucocytosis, however, was not a necessary manifestation of perforation or of inflammation. It was a manifestation of the reaction of blood to infections, biotic or toxic. It was often entirely absent in typhoid perforations.

Collapse was absent in duodenal perforation except when associated with severe hemorrhage. Collapse in intestinal perforation was the manifestation of the absorption of the product of infection, and not a manifestation of the perforation *per se.* Collapse was always secondary to abrasion or denudation of the endothelial covering of the peritoneum, which abrasion permitted of rapid absorption.

In all cases of perforative peritonitis, to which duodenal perforations were no exception, operation should be done at the earliest possible moment after perforation had taken place, and experience showed that the mortality was in direct ratio to the length of time that elapsed between the occurrence of perforation and the operation. In perforation the longer the escaping material was in contact with the peritoneum, the greater the danger of destruction of its endothelial covering, and thus the greater the danger of absorption. Of thirteen cases operated upon more than thirty hours after perforation, all terminated fatally, while in twelve cases, where less than thirty hours had elapsed, 66⅔ per cent. recovered. The operation must be complete—that is, it must be pursued to an effective suture of the perforation. Drainage was insufficient, as of eighteen cases treated by drainage alone all died. The suture of the opening can be easily inserted, as in 98 per cent. of the perforating ulcers into the peritoneum the opening was in the first portion of the duodenum, its most accessible portion. Where duodenal perforation was suspected, the incision should be through the right rectus muscle. It could then be carried upward to the costal arch, or downward to the symphysis pubis without dividing any of the transverse muscles. The incision through the rectus muscle was the one which he commonly made in operating for appendicitis. It could be enlarged upward or downward without interfering with the muscle fibers.

Drainage or no drainage was a matter of personal election, influenced, more or less, by the pathological condition present at the time of the operation.

The after-treatment was that commonly followed after abdominal section, except that the patient was kept elevated in bed at an angle of 35° for the first forty-eight hours after the operation.

The prognosis depended, first, upon the virulence of the peritonitis produced; second, the time the material had been allowed to remain in the peritoneum; third, on the presence or absence of blistering or abrasion of the peritoneum at the time of operation.

Peritoneal Tuberculosis.—The author, Dr. Rufus B. Hall of Cincinnati, Ohio, reported a few cases of operation for peritoneal tuberculosis, and made some remarks as to operating in this disease. He contended that tuberculosis of the peritoneum in women was not a rare affection. It occurred often enough to make it necessary to consider it in the differential diagnosis of all obscure diseases in the pelvis and abdomen. In a large majority of cases coming under his observation there were no appreciable manifestations of the disease in other parts of the body. The symptoms of this disease simulated several other conditions in the pelvis and abdomen, and it required patient and careful study to differentiate one from the other. The diseases most likely to be confounded with this affection were the recurrent attacks of appendicitis of the catarrhal form, small fibroid tumors, with old tubo-ovarian disease, and recurrent attacks of pelvic inflammation. An ovarian cyst of moderate size might be confounded with encysted dropsy. But he insisted that if the case was one of tuberculosis the temperature chart would suggest this disease if the temperature was taken every four hours for a period of ten to fifteen days. In no other condition was there the exact regularity in the afternoon rise of temperature as in tuberculosis. All cases of peritoneal tuberculosis in which there was encysted dropsy, or an accumulation of pus or serum, should be operated upon; after the necessary surgical repair the abdomen should be drained. He advocated vaginal drainage in women. First, because it gave perfect drainage; and, second, it prevented ventral hernia, which so often followed on account of the fact that the drainage tube must be kept in for so many days.

Of 110 patients operated upon by the author for peritoneal tuberculosis, twelve were for supposed appendicitis, four males and eight females. For other conditions he operated ninety-eight times on the female. Of this number two deaths were directly due to the operation. One died of meningitis on the seventeenth day; one died from general dissemination of the disease six weeks after operation; one died from general dissemination in ten weeks. These five cases all died in the hospital; one recovered in four weeks, left the hospital convalescent, and died two weeks afterward of meningitis after three days' illness. One recovered and left the hospital in the fourth week, and died in thirteen weeks after the operation from general dissemination. Eight died from tuberculosis in various forms in from fourteen months to four and a half years after the operation. Two cases were suffering from pulmonary tuberculosis and would probably die within a year. The remaining ninety were systematically well. A few of these cases had been operated on so recently that no conclusion could be drawn. Taking the cases as a whole, the results were gratifying beyond expectation. A large per cent. of the cases were enjoying the best of health, and from their appearance one would never suspect that they had had tuberculosis.

Surgical Treatment of Perforated Gastric Ulcer with General Infection of the Peritoneal Cavity.—Dr H Howitt of Guelph, Ont., stated that acute perforation with general infection of the abdomen was caused usually by the acute, round ulcer, but might occasionally take place in the course of the chronic ulcer, especially when it was situated on the ever-moving anterior wall. All the phenomena of acute perforation might result in either form of ulcer in a more indirect manner by the formation of a localized abscess, which afterward ruptured internally. The initial symptoms of acute perforation were described.

Treatment.- In a case of perforation with general infection of the abdomen medicinal remedies were useless as regards effecting a cure. Nothing short of early, bold, and thorough surgery could save the patient. A large irrigating tank, capable of throwing a stream almost an inch in diameter, expedited matters All sutures should be threaded beforehand, ready for instant use. When patient was anæsthetized an incision from ensiform cartilage to pubis should at once be made, bowels eviscerated and protected. Then the stomach was examined and the perforated part brought as far as possible out of the wound and the field guarded by sponges. The ulcer perforation might be excised, if considered advisable, but it was generally merely closed with two or more rows of silk sutures. Now, every pouch and corner in the abdomen was thoroughly inspected by sight and flushed clean. Three rubber drainage tubes were used, not one of which was placed in the wound, but through stabs, one at the back in each flank depression below the kidney, and one in the lower abdomen to the right or left of the incision for the pelvis. After the intestines were replaced and omentum was spread over them and fastened below the lower end of the wound with a suture or two, the incision was closed as quickly as possible and dressed. In a desperate condition of the patient, a pint of peptonized milk or other suitable liquid food was injected into the jejunum during operation.

After-Treatment.—Suitable measures to combat shock. Patient was supported for first week by rectal enemata and nothing by the mouth but sips of hot water. No morphine should be given unless it was evident that death was inevitable The bowels were to be regulated by injections of magnesia sulphate in solution.

In the paper reference was made to his first case, in which the operation was performed on February 20, 1900, and in which, owing to stenosis of the pylorus, gastroenterostomy was done. The patient, a farmer, enjoyed excellent health until the third of the present month, when he was suddenly ceased with intense pain in the abdomen near the umbilicus, which gave rise to well-pronounced shock. At the operation the proximal arm of the bowel close to the site of anastomosis was found perforated by a round, peptic ulcer. The patient was now practically well again, and had not had a single bad symptom. It was noticed at the last operation that the gastroenterostomy by dragging of the bowel had caused the stomach to become triangular in outline, the lower angle of which was close to the left side of the umbilicus.

It was claimed that this was the first time that an operation for a perforated ulcer of the jejunum, as a result of gastroenterostomy, had been reported in America.

His second case of acute gastric perforation occurred in a young woman, aged twenty-one years, who had never had any serious illness. The attack came on suddenly without a previous symptom of gastric ulceration. In this case the situation of intense pain at the onset was in the epigastrium, and two hours later in the lower abdomen. A large perforation was found in the posterior wall of the stomach close to the lesser curvature. It was very difficult to close the perforation, owing to the situation. The lesser peritoneal pouch, the depression in both flanks, and the pelvic cavity were filled with pus, which contained pieces of partially-organized lymph. Patient made an uneventful recovery, and had never since had any illness, nor even gastric distress.

In conclusion, the essayist stated that he was aware that many surgeons strongly objected to evisceration in abdominal work, but maintained that in the conditions under discussion it was impossible by any other known method to make certain that the toilet of the peritoneum had been done thoroughly, and said that imperfect toilet was followed by more shock, and was vastly more dangerous than hours of properly-managed evisceration.

Carcinoma of the Cervix Uteri.—Dr. L. H. DUNNING of Indianapolis, Ind., read a paper on this subject, in which he presented a summary of his sixty-two cases operated upon by hysterectomy. These cases showed on applying the accepted test of time—five years—that the author had had an encouraging number of cures; they also showed the desirability of early operative procedure. The operative methods employed were indicated, and the author's views of the same were discussed. He reported five cases of carcinoma of the cervix uteri in which the women were alive five years after hysterectomy.

CASE I.—Mrs. A., referred to him in January, 1892. The patient was sixty-three years of age, and had reached the menopause ten years previously. For several months she had had profuse uterine hemorrhages. Dr. Terrill had removed small growths from the cervix uteri several times, but new ones had quickly sprung from the site of the former ones. At the time of his (Dunning's) examination, there was a small cauliflower growth springing from the cervix and protruding into the vagina. A portion of it was examined by Dr. Ferguson and pronounced carcinoma. Vaginal hysterectomy, with extirpation of the appendages, was done January 4, 1892. The patient recovered.

CASE II.—Mrs. B., married, and aged thirty years. She was emaciated, as a result of uterine pain and hemorrhage. A neoplasm was found, involving the cervix uteri. A portion of the growth was examined and pronounced carcinoma. A total extirpation of the uterus and appendages was done January 30, 1896. The patient recovered.

CASE III.—Mrs. C., aged forty-five years; examined by him December 2, 1896; she gave a history of frequent and profuse hemorrhages, and now had a thin fetid discharge. Examination disclosed a small papillomatous mass upon the posterior lip of the cervix. A piece was snipped out, examined microscopically, and pronounced carcinoma. Vaginal hysterectomy was done December 3, 1896. The uterine appendages were also removed. Recovered.

CASE IV.—Mrs. D., forty-eight years of age, mother of four children, youngest seventeen years old. Upon examination, a neoplasm, involving one-half of the circumference of the cervix uteri, was found. Microscopic examination showed it to be a squamous-celled carcinoma. Hysterectomy was done April 16, 1896. Patient made an excellent recovery.

CASE V.—Mrs. E., aged forty years; married and mother of two children. Microscopical examination of cervical neoplasm was made by Dr. Hodges, who pronounced it carcinoma. A vaginal hysterectomy was done October, 1895. Patient was in ill health for some months following the operation, but has recovered. The essayist examined patient in July of this year and found a clean vagina, with no signs of recurrence.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. L. H. Dunning, Indianapolis, Ind.; *First Vice-President*, Dr. Marcus Rosenwasser, Cleveland, O.; *Second Vice-President*, Dr. Herman E. Hayd, Buffalo, N. Y.; *Secretary*, Dr. William Warren Potter, Buffalo, N. Y.; *Treasurer*, Dr. X. O. Werder, Pittsburg, Pa. Chicago, Ill., was selected as the place for holding the next meeting; time, September, 1903.

The Value of Electrolysis in the Eustachian Tube.—N. H. Pierce offers the following conclusions: (1) In otosclerotic disease, electrolysis is useless; (2) In the great majority of cases of catarrhal disease, it has no advantages over other methods of treatment; (3) In a certain few cases where there is probably a soft exudate near the isthmus, it may be regarded as of some value.—*Archives of Otology.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PRINCIPLES AND PRACTICE OF GYNECOLOGY. Third edition. By E. C. DUDLEY, M.D. 8vo, 761 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa. Price, cloth, $5.00 net. Leather, $6.00 net. Half morocco, $6.50.

DISEASES OF THE RECTUM AND ANUS. By SAMUEL G. GANT, M.D. Second Edition. Royal 8vo, 687 pages. Illustrated. F. A. Davis Company, Philadelphia, Pa. Price, cloth, $5.00; sheep, $6.00.

Points on the Malaria of Southern Italy.—F. Martirano describes an epidemic of malaria in Cetraro, in which the part played by the anopheles seemed to be very small, indeed. He calls attention to the fact that the mosquito is not the only agent in malaria, a part only, and that part, the shortest of the life of the parasite, being spent within that insect. The longest part, and the least well known to scientists, is that spent in man. It is probable that the vitality of the parasite is much greater than has hitherto been supposed, and that during the malarial season not only do the anopheles become infected with the gametes of malarial relapses, and propagate the disease from the infected to the previously healthy, but that there is a renewed activity in the multiplication of the parasites within the organism of patients who have been previously affected with the disease. The human equation in malaria deserves further research.—*La Riforma Medica.*

Contagious Diseases Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 27, 1902:

	Cases	Deaths
Measles	37	.
Diphtheria and croup	199	25
Scarlet fever	84	4
Smallpox	5	1
Varicella	14	..
Tuberculosis	237	141
Typhoid fever	..	23
Cerebrospinal meningitis	.	1

The Dangers of the Menopause.—Sara E. Greenfield says that the climacteric, or cessation of menstrual life is nature's first warning of old age. In order of frequency, the nervous manifestations stand first. The patient becomes irritable and easily fretted by little things. She is troubled with indigestion, insomnia, hot flashes, cold feet, palpitation of the heart, etc. If she is at all of a melancholy turn of mind, she will develop all kinds of phobias. It is best for the physician to take her into his confidence and explain to her why all these disturbances exist. Sodium bromide is an excellent nerve sedative, which produces no harmful after effects even when it is used for a long time. Iron and other blood builders are indicated. Rest is of the greatest importance. If the patient cannot be sent away from home, then she should take a few hours of rest every day, even though she cannot sleep at this time. Next in frequency to the nervous systems, and often accompanying them, is an increased menstrual flow. The physiological process of the menopause is atropic, and there should never be an increased menstruation. The most common causes of menorrhagia are: Metritis and endometritis, uterine fibroids, relaxation of the uterine tissues, and carcinoma. In these four conditions, increased menstruation is practically a constant symptom. In the majority of cases the problem of differential diagnosis is limited to the aforesaid diseases. Metritis is the most common cause of menorrhagia. In chronic cases, and in long-standing hyperplasia, there should be a thorough curettage. Surgeons should think twice before performing the radical operation for a uterine fibroid. In cases of prolonged or increased flow, with no other symptoms, the writer gives a combination of ergot, viburnum, and aromatic sulphuric acid with excellent results. Lastly, she considers cancer. There is little to expect, now, in the way of improved surgical technique, and hope lies in the earliest possible diagnosis. From a clinical standpoint, we find probably very little of anything besides the irregular menstruation in an early case of carcinoma of the cervix. The writer has no faith in a diagnosis made from uterine scrapings. It is necessary to remove a small wedge of tissue, put it into a bottle of 60 per cent. alcohol and send it to some one who does reliable microscopic work. Delay at this time is fatal. The disease has always extended farther than is apparent to the naked eye. The lymphatics are quickly invaded, and the disease becomes systemic oftentimes before the physician has made up his mind to act or before the patient has given her consent.—*The Woman's Medical Journal.*

The Customary Therapy of Kidney Diseases. Carl v. Noorden first discusses acute nephritis. He believes that it may be said that in practice the administration of an exclusive milk diet occupies so important a place in the treatment of acute nephritis that it has replaced all other systems. For the sub-chronic form of nephritis with œdema, essentially the same dietetic treatment has been introduced and maintained. But in th[illegible] a pure milk diet cannot be administered [illegible] as it can in the acute forms. Occasionally, the disease runs a favorable course in patients living on a pure milk diet. As a rule, patients who cannot bear the milk [illegible] allowed to eat small quantities of meat, preferably [illegible] one or two eggs a day, and, besides, some vegetables, fruit, cereals, butter, and sugar. Strong condiments, alcohol, and stimulating drinks of all kinds should be prohibited. The dietetic régime in chronic nephritis varies considerably, but here also there are enthusiastic adherents of the exclusive milk diet. Most authors admit that it is best not to exclude meat and eggs from the diet of patients suffering from atrophic nephritis, although restrictions must be imposed, as to both the quantity of meat and eggs allowed and the form in which they are to be given. Raw eggs are usually forbidden; the white part of meat alone is permitted (chicken, veal, pork, hare, fish), or at least recommended. Raw and stewed fruits, cereals, legumes, and fats are generally allowed without restriction; most vegetables, except radishes and those containing irritating oils, are allowed; asparagus is generally forbidden. All strong spices are bad, and so is vinegar. Lemon juice may be used instead of the latter. The principle of treatment is to save the diseased organs as much as possible. In order to know what diet really does spare the kidneys, we must, in the first place, study the results of general clinical experience. A second important criterion is the degree of albuminuria. The absolute quantity of albumin voided in the urine in twenty-four hours should be estimated. A third point is the excretory power of the kidneys. The only way to determine the power of elimination of the kidneys in regard to normal excretory products, is to test the elimination of these products themselves. Only in a small number of cases do the elimination of drugs and of natural matabolic products go hand in hand.—*International Medical Magazine*

The Johannesburg Bread Supply.—Dr. Charles Porter, says the *Medical Magazine*, has just issued a report on the above subject and has laid bare a most unsatisfactory state of matters. His inquiry revealed the fact that about 85 per cent. of the bread sold was under weight, and that over 65 per cent. was of bad quality, either containing alum, or an excess of acid, or being sour or badly baked. With the exception of the water supply, and in some cases the ventilation, the sanitary condition of the bake-houses did not call for much improvement. But the first-named requisite, water supply, was faulty, in many instances being from shallow wells open to pollution. Dr. Porter advised that a public supply should be laid on to the defaulting bake-houses, and that in the mean time all water used should be boiled.

Resuscitation of the Stillborn.—Rhythmical traction of the tongue has been highly lauded as a substitute for artificial respiration in attempting the resuscitation of apparently still-born infants, but this procedure, though of unquestionable utility, has the drawback of being somewhat difficult of application in these cases on account of the difficulty of obtaining and retaining a firm grip on the little tongue. As an alternative it is pointed out that rythmical pressure on the base of the tongue by the finger introduced through the mouth answers the same purpose, and at the same time it has the advantage of freeing the upper air passages from any accidental cause of obstruction.—*Medical Press.*

A Javanese Anæsthetic. Mr. L. Steiner, writing in a recent number of the *Semaine Médicale* asserts that it is sometimes customary for healers in that country to place their patients in a profound anæsthetic sleep, by compressing the carotid arteries. The practice, according to the writer, is much resorted to in the east of Java, where the treatment is known as *tarik urat tidor*, that is, "compression of the soporific vessel." Mr. Steiner declares that he himself successfully induced deep anæsthesia by this method, so much so that in one case he was able to lance an inguinal abscess without the knowledge of the patient.

Diseases of the Ear in Hysterical Subjects.—The views of Prof. Voss are summarized in the following propositions: (1) The objective picture of an acute otitis media may appear as a symptom of hysteria. (2) Pure functional neuroses of the ear should be treated, not by an otologist, but by a neurologist. (3) In these cases an absolute contraindication exists against too much treatment, especially of the nose and pharynx. (4) The generally well-known craving of hysterical subjects for operations may also center upon the ear (and, probably, also upon the nose). (5) Opening the mastoid process to relieve the mastalgia of hysterical patients is absolutely contraindicated. (6) Our present method of after-treatment of radical operations with prolonged tamponing is not at all suitable for children or nervous and hysterical patients. After the fifth day the tampon is entirely superfluous and should be replaced by a simple outer dressing.

Pulmonary Embolism.—George S. Mathews says that the present status of thrombosis may be briefly summed up in the statement that blood platelets begin the formation of a thrombus. They accumulate in a viscid mass, and with a slowing of the blood stream leucocytes are enmeshed, fibrin ferment is produced, erythrocytes are entangled, and we have a complete picture of a thrombus. Four cases of pulmonary embolism are reported by the author, in three of which phlebitis was the origin of the thrombosis. Given an impoverished condition of the blood, added to an endophlebitis, and we have the conditions favorable to the formation of a thrombus. One of the cases reported is of thrombosis in chlorosis.—*The Providence Medical Journal.*

The Formation of Phenolsulphuric Acid in the Organism.—L. Laudi concludes from his researches: (1) That when phenol is given by the mouth, phenolsulphuric acid is formed by the biochemical activity of the cells of the digestive tract, and it is, therefore, probable that the acid derived from the digestion of the food is produced in the same way. (2) The liver has an analogous action, excepting when a part of the phenol reaches it in an unaltered condition, in which case the organ acts (secondarily, as it were) on the defensive. (3) When phenol is injected hypodermically, the acid is formed without the intervention of the intestines, probably in the liver, and, possibly, in some other organ also. (4) Phenol may pass unaltered in the urine, but only in very small doses.—*Il Policlinico.*

Suicide in Germany.—The total number of suicides in the German Empire recorded in 1900 was 11,393. Of these 8,987 were male and 2,606 female, a proportion of 100 of the former to 26.8 of the latter. Among the 108,404 persons who committed suicide in the German Empire during the past decade, the proportion of males to females was 100 to 26.3. The statistics of suicide for 1900 show a proportion of 20.3 suicides to 100,000 inhabitants. For males alone the proportion was 32.6; for females 8.8.—*British Medical Journal.*

Professions and Lunacy.—A French investigator has come to the conclusion that the brains of naval and military men give out most quickly. He states that out of every 100,000 men of the army or naval professions 100 are hopelessly lunatics. Of the liberal professions, artists are the first to succumb to the brain strain, next the lawyers, followed, at some distance, by doctors, clergy, literary men and civil servants. Striking an average of this group, 177 go mad to each 100,000.

Brooklyn School Inspection.—Healthy children only are to be admitted to the Brooklyn schools. A special corps of physicians will visit each classroom and will exclude from attendance in classes all children that exhibit evidences of contagious disease, such as acute catarrhal conditions of the eyes, nose and throat, and parasitic diseases of the skin and scalp.—*Public Opinion.*

Rheumatism in Nyassaland.—Rheumatic fever is reported by Dr. Kerr Cross to be very common in North Nyassaland. That it differs somewhat in its results from the English type of the disease may be inferred from his additional statement that many of the joints are permanently affected by this disease.—*London Polyclinic.*

Braithwaite's Retrospect of Medicine.—Braithwaite's Retrospect of Medicine has come to the end of its useful career. The first volume was issued in 1840, and the publication continued to appear regularly till last year. The 123rd volume, dealing with the year ending June, 1901 was the last of the series.

University of Moscow.—The total number of students already entered on the books of the University of Moscow for the academic year 1902–'3 is 968. Of these 214 belong to the Faculty of Medicine.

The Gouty Constitution.—Arbuthnot says that a gouty constitution is attended with great acuteness of parts, the nervous fibres of the brain and the other extremities being delicate.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Public Health and Marine Hospital Service, during the week ended Sept. 27, 1902:

THE PROMINENT EYE.

ITS MEANING AND CLINICAL ASSOCIATIONS.

BY A. HAIG, M.D., F.R.C.P.,
LONDON, ENG.

WE all know the prominent eye of exophthalmic goiter, or Graves' disease, and the prominent eye of which I speak in this paper is but a minor condition of the same thing.

But while the full picture of Graves' disease is somewhat rare, the prominent eye or some degree of this condition is rather common, especially among the uric-acid feeding upper classes, and is to be seen, perhaps, in one or two out of almost any ten people we meet.

The underlying cause common to Graves' disease and minor conditions of prominent eye is high blood pressure, and in this paper I am treating of the prominent eye as a valuable and readily-observed symptom of high blood pressure, which again, as I have elsewhere shown, is due to the presence of uric acid in the blood.

With the exception of certain alterations in the eyeball itself, such as those of myopia, which can easily be identified, or certain new growths or tumors in either the eye or neighboring structures, blood pressure is the chief determining factor in the prominence or retraction of the eyes.

To take extreme cases, we have the prominent eye of Graves' disease with blood pressure—say, 150 mm. of mercury or above—on the one hand, and on the other the sunken eye of the young child dying of diarrhœa and collapse, with blood pressure probably 50 mm. of mercury and below, and here we have also the cold extremities, the shrunken skin, and, perhaps, the deeply concave fontanelle to tell the same tale of diminished blood pressure. Between these great extremes we get all varieties of intermediate conditions, so that, in clinical medicine, the position of the eye is a ready guide to the vascular condition of the patient, and its value is increased by measuring even roughly the extent of the prominence, or retraction, and noting the other signs of the vascular conditions to be seen in the face with each position of the eyeball. As I have elsewhere pointed out,* Graves' disease may, if taken in time, be relieved or even cured by removal of the high pressure, or its cause—uric acid collæmia. The symptoms of Graves' disease are too well known to need description, but I will merely mention in passing that of its three cardinal symptoms the prominent eye is met with very frequently in the high-blood-pressure headache (migraine or uric-acid headache), that enlargement of the thyroid occurs in most women during menstruation when the blood pressure is raised, and when those of them who suffer from migraine or epilepsy have their attacks, and that the quick pulse is met with in all similar high-blood-pressure conditions, as the heart begins to fail before the high pressure. Graves' disease is, in a word, as I have already suggested, but an exaggeration of some of the common signs of high-blood pressure.

Thus I know several sufferers from uric-acid headache who have attacks with each menstrual period, and with each of these attacks the neck enlarges so that for a day or two their ordinary clothing cannot be used; and no doubt it is this monthly fluctuation in collæmia and its resultant blood pressure that accounts for the fact that exophthalmic goiter is chiefly seen in women, and that those who are weak, or nearing the period of life at which the heart tends to fail, may have more or less palpitation and quick pulse with each such periodical attack; and in my work on "Uric Acid," fifth edition, p. 139, I have recorded a case in which a man who suffered from migraine presented a similar cycle of events, according as his heart failed under strain or recovered with rest and tonics. When his heart was strong he had headaches and prominent eyes and enlargement of the thyroid; when his heart failed he lost his headaches, and the prominence of his eyes and of the thyroid diminished.

I will merely add that in all these conditions of Graves' disease, or developing or partial Graves' disease, in which the prominence of the eyes is well marked, blood pressures of 150 mm. of mercury and above are the rule.

Now, if a normal eye is closed and a card is held vertically over its center its edge will rest firmly over the supraorbital ridge above and the malar and superior maxillary bones below; but it will touch the eyeball so lightly as to cause no discomfort.

On removing the card a pale line is seen where it has pressed the blood out of the skin over the bones; but it has hardly affected the skin of the eyelid at all. And this is no doubt the natural position of the human eye, for the bony boundaries of the orbit now afford it efficient protection from pressure and injury, and this is its position when the blood pressure is normal.

When, however, the card is applied in the same way to an eye which is too prominent, it rests on the front of the ball and rocks up and down over it, only touching one of the edges of the orbit. It makes a pale mark on the eyelid and causes painful pressure on the eyeball without touching both the upper and lower borders of the orbit at the same time.

Then when one looks at a face in which the eyes are markedly prominent one sees the whole side of the face forming a cone, of which the apex is the front of the eyeball.

In a normal face there is an upward and forward slope to the lower margin of the orbit; then there is a crateriform depression, and the ball of the eye projects more or less from the center of this. But in the face with the very prominent eye the depression above the margin of the orbit is done away with, and the cone is continued up without a break to its apex at the front of the eyeball. The eye is so prominent that the lids stretch forward over it, obliterating the normal depression at the margin of the orbit.

And there is here, I think, a point of difference between the eye of exophthalmic goiter and the prominent eye I am now seeking to describe; for the eye in Graves' disease becomes prominent more

---

*Uric Acid Ed. V., p. 140, *et. seq.*

less suddenly, so that the eyeball leaves the lids behind, so to speak, and they fail to cover it, to anything like the normal extent; but in the prominent eye of chronic high blood pressure there has been more time, the change and increase of prominence has been gradual over years, and the lids have been able to follow the eyeball and cover it to a greater extent than in Graves' disease.

Among concomitant signs of the prominent eye the most important is a distended condition of the skin, whether it be with fat, blood, or serum, or all three more or less mingled; the wrinkles tend to disappear or get smoothed out, and the whole skin of the face gives the idea of distention and puffiness.

This is well seen in a woman of, say forty-five years; the stout body gives an idea of distension, the skin of the face is puffy and tense, the eyes stand out, and the sides of the face slope up to them with hardly any indication of the whereabouts of the orbital margin; with such signs at such an age it is pretty safe to say that the blood pressure is not below 150 mm. of mercury.

Some minor conditions which may be seen with some stages of the prominent eye are a distended condition of capillary vessels, giving a dark streaking of color, very different from the delicate flush of health, in which no vessels are visible.

Then, as time goes on, the tense skin and prominent eye gradually give place to a more wrinkled skin, and an eye which, though still prominent shows now the margin of the orbit surrounded by more or less large folds of eyelids, as the previous stretching is relaxed, and this probably comes at an age when the hair is becoming markedly gray or even white.

Later still we get an eye, hardly prominent at all, with a skin still puffy, but in wrinkles and folds, and the color in the distended skin vessels becomes dusky and irregular, almost blotchy, as heart weakness and venous congestion increase. And at last, near the final stages of heart failure, of which the above are intermediate stages, we see the face becoming pale, and the blood even falling out of the distended and degenerate vessels, which gave the face for so many years what was often thought by the man in the street to be its hue of ruddy health; but which was in reality the stamp of vascular degeneration and decay.

With wrinkled and still puffy skin, a sunken eye, an orbital margin surrounded by loose folds, with a paling surface and a shrunken appearance, we get a quick, irregular, or intermittent pulse, and a blood pressure but little over 100 mm. of mercury.

Thus a woman in front of us has eyes that are distinctly prominent, a skin which is puffy, a face and figure which are decidedly stout and give an idea of distention. An older woman with gray hair, who sits beside her probably her mother, has a somewhat puffy skin, but her eyes are retracted rather than prominent, and her pale face, wrinkled skin, and wasting figure, tell a tale of heart failure and falling blood pressure. A single glance at these two tells us which has the lower blood pressure and why.

Or, again, one sees a woman who is obviously too excitable, and in her face the eyes are somewhat prominent, and the skin puffy, but round and below the eyes are large, loose folds of skin, and here we can see the whole history of cause and effect. Her blood pressure is high, and it has been high for a long time, and has been higher also than it is now. As her hair has grown gray, her heart has failed, the eye has become less prominent and surrounded by large loose folds of skin, and we already know that heart failure with its accompanying fall of blood pressure is a cause of mental excitement, even of mania.

Or, still again, one sees a man with exactly the above facial signs, and he tells us that for years he has suffered from periodical headaches, but that of late he has had less headache but some palpitation; his face tells us what his palpitation tells us, that his heart is failing, and that, blood pressure not being maintained, headaches due to it are not so severe.

Prominent eye is most common and most marked at about forty-five and fifty years of age, for then the heart attains its greatest hypertrophy; but it may be seen in early age, and I recently had among my out-patients a child of nine or ten years with this sign fairly marked, and its mother had it still more developed, for both were sufferers from high-blood-pressure headaches.

Thus those who have high blood pressure tend to have prominent eyes from the time they are full grown, from the time, that is, when the heart attains its full power, and here we have no doubt one reason why the headaches and epilepsy of high blood pressure start into prominence at puberty.

This continues onward through life. The eyes attain their greatest prominence in middle life, just when the heart is strongest, and gradually become less and less prominent as the heart fails with advancing years.

Then if in two cases the obstruction to the circulation is equal, the eyes will be most prominent in that which has the stronger heart; and, indeed, I believe it is in many cases possible to gauge approximately the thickness of the left ventricle simply by the greater or lesser prominence of the eye.

Then, naturally, conditions which hinder the circulation through the lungs, such as bronchitis, asthma, and emphysema, will make the prominent eye still more prominent, for such conditions not only directly obstruct the circulation, but defective oxygenation of the blood is a cause of collæmia, and it is also a cause, both direct and indirect, of obesity.

In the same way coughing, straining, and heavy exertion, as lifting, raise the blood pressure and increase the prominence of the eye. On the other hand, deep breathing lowers the blood pressure and diminishes the prominence of the eye; hence breathing exercises frequently practised when unrestrained by clothing are good for all those who suffer from high blood pressure and obesity; while those who suffer from obesity and insist on keeping their clothing tight are only increasing their trouble.

Mental excitement also raises blood pressure, and will therefore increase the prominence of the eyes.

On the other hand, absence of the above troubles and the presence of good respiratory powers may, to some extent, mask the effect of blood pressure on the eye and render it less prominent than it otherwise might be; but good respiratory power also tends to prevent very high blood pressure, and to diminish the tendency to obesity.

Then a tendency to stoutness will no doubt increase the prominence of the eye and the distention of the whole face and body; but high blood pressure is a wonderfully constant concomitant of obesity, so that I have long regarded obesity as a sign of high blood pressure, or rather as one of the results of the defective circulation which causes the high blood pressure; hence we so often find obesity accompanied by glycosuria or albuminuria. These are all merely forms of defective combustion due to defective capillary circulation, and they tend to occur together because they are results of one common cause, and the prominent eye is the facial sign of the first effect of this cause—high blood pressure.

Then, in estimating the actual prominence of an eye, we must remember that folds of puffy skin round the orbital margins may make it appear less prominent than it really is, and in such cases we must take care to feel the margin of the orbit and gauge the position of the eyeball in reference to this; but, allowing for these things and for differences of face and form and of size and prominence of bony ridges, there is no doubt that the position of the eye is often a most valuable guide to the blood pressure of its possessor. As I have already for some years been pointing out, the one cause of defective capillary circulation and high blood pressure is collæmia or excess of uric acid in the blood, therefore this is the cause of all the conditions we have here been considering, and the prominent eye, with some of its associated facial conditions, is a very constant sign of this collæmic circulation, and far more contsant than some of its better known results.

It is not everyone who has high blood pressure from collæmia that suffers from headache; it is only those who have a certain size and arrangement of vessels at the base of the brain; and again in those who do suffer there are all variations as to the height of blood pressure at which they begin to suffer. Thus some suffer at anything over 130 mm. of mercury, others only at 160, and others again will have little or no headache even with the highest blood pressures we know of.

Again not everyone that has collæmic high blood pressure will suffer from asthma, or glycosuria, or albuminuria. These may be present only when some concomitant condition precipitates the chief stress of the altered circulation on the lungs and bronchi, the liver, or the skin, respectively; but the one underlying condition common to all is collæmia and the high blood pressure it produces, and more or less prominence of the eye is a wonderfully good and constant index of this condition.

The prominent eye not only tells us whether there is high blood pressure, but it will often tell us also how long it has been there, and whether the heart has slowly and steadily hypertrophied under it, or has failed early, before much hypertrophy was possible, or only later, after it had for years kept up a very high blood pressure.

And when we observe not only the prominent eye but the condition of the skin round it, whether it is tense and smooth over an organ almost starting from its socket, or hanging in folds round a less prominent organ, or again wrinkled and atrophied, but still unduly lax over an eye scarcely prominent at all, I think we can often read in the patient's face not merely high blood pressure or low blood pressure, more or less, but no unimportant part of the life history of his vascular system.

Inflammation of the Diaphragm Complicating Pneumonia.—C W. G. Rohrer holds that inflammation of the diaphragm is a common complication of pneumonia. In most of those cases in which it is not found post mortem it will be observed that the specimen was obtained from a part of the diaphragm remote from the inflamed lung. Extension of the inflammatory process from the pneumonic lung to the diaphragm takes place (*a*) by direct extension, (*b*) by the lymphatics, (*c*) by the blood-vascular system. (2) The inflammation of the diaphragm is due, in large part, the so-called "pleuritic stitch-pain," also a pain in the abdomen often complained of, especially by children. The dyspnœa of frequency, always present in pneumonia, is due, in large part, to the patient's efforts to restrict the movements of the diaphragm. (3) The inflammation especially involves the muscular substance of the diaphragm, and may be mild or intense, in keeping with the grade and extent of the pneumonic condition. It is of bacterial origin, the usual microorganism being the pneumococcus.—*Maryland Medical Journal.*

RESECTION OF NEARLY EIGHT FEET OF GANGRENOUS INTESTINE—RECOVERY.*

By GEORGE R HARRIS, M.D.,
NORWICH, CONN.

The removal of large portions of the intestines, with recovery of the patient, is becoming much more common than in former years, and when there is an abundance of time in which to prepare the patient, with plenty of assistance and good light, this operation is robbed of many of its difficulties; but when, on the other hand, the operation is performed in an emergency, after the patient has been brought a long distance in an ambulance, he being more or less exhausted, with a violent peritonitis in progress, it is an entirely different thing.

These circumstances, together with the extreme length of the intestine removed, and the apparent complete recovery of the patient, are my reasons for reporting this case. The history is as follows:

On September 11, 1901, I was called by Dr. Ashley of Colchester to Salem, Conn., about twelve miles from Norwich, to see a man who was said to be suffering with an obstruction of the bowels, possibly intussusception. The patient was Mr. B. L. P., aged thirty-three, U. S., married, sculptor; a man weighing about 140 pounds, dark complexion, black hair, smooth face, fairly nourished, with little fat, and very muscular. His family history was negative. He had had the usual diseases of childhood, and typhoid fever eight years ago, but had been perfectly well ever since, except that for several years he had had, at times, attacks of severe pain in the abdomen.

In 1897, in Paris, he had an attack which lasted about fifteen minutes and was relieved by massage. Two years later, in the middle of the night, he had a similar attack, which was again relieved by massage. Nearly a year later he had another attack which did not last long, and which passed away on his keeping quiet in a reclining position. Last summer he had an attack which was relieved by Jamaica ginger and massage, but lasted about half an hour. When these attacks have occurred they have been sudden in their onset, and immediately before and after them he has been apparently in perfect health.

On September 10 he played a hard game of golf in Norwich and then drove twelve miles to his home; retired that night feeling perfectly well, arose the next morning and prepared to go hunting. In a little while he was taken with an exceedingly severe pain, which centered in the umbilical region. He took some brandy, returned to bed, and massaged his abdomen thoroughly, and in a short time was entirely free from pain, and slept about an hour. On arising, his pain commenced again, even more severe than before. Massage was of no avail. He had a large movement, but the pain was not diminished. Dr. E. F. Ashley of Colchester was called at 9 A.M. and administered one-quarter grain of morphine sulphate, hypodermically, and repeated the dose at 9.30. Mr. P. gave the history of having eaten a number of half-ripe peaches the night before.

Upon examination of the abdomen the doctor found an area of extreme tenderness about the size of the palm of the hand, to the left and above the umbilicus. No tumor was evident. The patient had vomited, but the vomited matter consisted only of fluid with mucus. Large enemata of hot water were given with no result, the fluid returning clear with the exception of some small particles of fecal matter and some mucus spotted with blood. Hot applications were made to the abdomen, but the

*Read before the Connecticut State Medical Association, 1902.

pains still continued. At 11 A.M. his temperature was 97.4° and his pulse normal.

Upon my arrival, at about 3.30 P.M., I found the abdomen fairly soft and with no special tender spots, except that on pressure in the neighborhood of the umbilicus the patient said there was some increased pain. On percussion I could get nothing decisive, except that over this tender area there seemed to be tympanitic resonance of high-pitched metallic quality. The patient's pain, which was considerable, was referred to the umbilicus. He was given several large enemata of hot water, but with absolutely no result, the water returning perfectly clear. It was now decided to do an exploratory operation, and there being no conveniences for such an operation at hand, he was sent to the Backus Hospital at Norwich, where he arrived about 1.30 A.M.

On his arrival at the hospital the patient said that his pain was not nearly as severe as when I saw him last at 5 P.M., and he also said that what pain he did have was in a new place, being to the right of median line and in the region of the appendix. He complained greatly of a severe pain in his right shoulder, for which he could account in no way except that in coming to the city he had lain on his right side in the ambulance all the way, about twelve miles, and the road was very rough. His pulse, however, was considerably quicker and weaker, being 120°, and his temperature had gone up to 100.6°. His face had a dark flush, his eyes were very bright and sunken, and he was very nervous and thirsty.

He was put on the table and his abdomen was examined. It was now very hard and tense, with no specially tender points. I could get nothing definite on palpation or percussion, although there did seem to be some slight dulness in the extreme right upper iliac region. The tympanites had disappeared. The abdomen was thoroughly cleansed and, being influenced by the patient's statement as to the location of the pain, together with the slight dulness found there, I made a small incision, sufficiently large to admit the index finger, over the appendix.

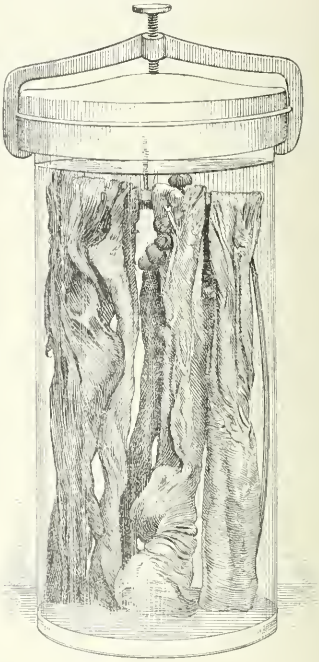
As soon as the abdomen was opened there was a tremendous gush of blood-stained serum, the stream rising fully ten inches from the surface of the wound and continuing for several seconds. A very large amount of fluid escaped; the fluid was serum, containing a large amount of blood and lymph, showing that an acute peritonitis was in progress.

On exploration with the index finger, I found a large mass of intestines, which were bound down in the right iliac region, and something entirely different from appendicitis; so the wound was closed and the abdomen was reopened in the median line when a very large mass of black and gangrenous intestines appeared. These, as stated above, were bound down in the right iliac fossa close to the cæcum, which was drawn toward the median line. This mass was about seven inches in the transverse diameter, and the coils of which it was composed, ran for the most part transversely; a few, however, were parallel with the long diameter of the abdomen. The point of constriction was close to the posterior abdominal wall and to the cæcum.

Some time was lost trying to uncoil the intestines, but this being found impossible, the constricting band, which was dense and heavy and about the size of a lead pencil, was divided and the intestines were spread out in hot towels and allowed to remain for over twenty minutes. The band, in the meantime, was examined. It could be enrolled and stretched out and appeared to be mesentery, with the inner border quite thickened and firm, and the rest of it membranous.

The intestine was now examined and found to be the ileum. The color was not improved; the gangrenous portion commencing at the cæcum and extending for a long distance up the ileum. The mesentery in many places was sloughing and entirely gone. There was one spot in the intestine where a perforation had taken place, but I do not think there was much extravasation.

The intestines were covered with lymph, and some slight adhesions had taken place between the coils. The ileum, having been previously clamped, was divided close to the cæcum, the remaining vessels of the mesentery were tied and trimmed away close to the spine; and above, the ileum was divided one inch from the upper limit of the gangrene an assistant holding the upper end.



INTESTINAL SEGMENT REMOVED; TOTAL LENGTH, SEVEN FEET TEN INCHES.

The whole mass of gangrenous intestines, with adherent strips of mesentery, was now removed from the abdomen. The abdomen was thoroughly flushed out with hot salt solution, and preparations were made for joining the intestines. The opening in cæcum was closed, the edges being inverted and closed with a double row of Lembert sutures, one-half of a Murphy button being first put into the cæcum. This button was then pushed against the wall on the other side of the cæcum beside the appendix, and, an opening being made, the button was brought through and held by an assistant. The end of the ileum was inverted and closed by a double row of Lembert sutures, the second half of the button having been previously placed in the bowel. This was brought through in the same way as the other, and the intestine was joined to the cæcum by a lateral anastomosis. No additional sutures were required, except a row in the mesentery.

The abdomen was now again thoroughly flushed out and closed, the different layers being united separately, and the wound was dressed with wet bichloride dressing. The portion of intestine removed measured seven feet ten inches. The time of operation was about one hour. Only two assistants, Dr. L. H. Bremmerman, House Surgeon, and Dr. N. P. Smith, who accompanied me to Salem and saw the patient there, besides myself, touched the abdominal cavity.

The patient stood the operation very well, considering the large amount of intestine removed. At one time his pulse became weak, and he was given a hypodermic of 1-30 gr. strychnine sulphate, and also a hypodermoclysis of salt solution beneath the breasts. He was placed in bed and surrounded by hot water bottles, and a saline enema was given and ordered to be repeated every two hours. Pulse was 154, respiration 22, temperature 100°. He was very restless on coming out from under the ether and very weak. He vomited frequently throughout the night small quantities of dark-brown fluid. The temperature ranged from 100° to 101.6° and back to 99.2°; the pulse varied between 128 and 154, and the respiration from 14 to 42.

He vomited continually the same brownish green fluid. Enemata were expelled clear; no gas. Strychnine was continued, and heroin, gr. one-twelfth every three hours, was tried to quiet him and control vomiting, but with no effect. Ingluvin gr. x and bismuth subnit. gr. xx every hour were also tried with the same negative result. The following day the same medication was continued, and, in addition, the stomach was washed out with saline solution, washing being continued until the return flow was perfectly clear. He was also given two nutritive enemata during the day, consisting of the whites of two eggs, brandy one ounce, peptonized milk eight ounces, and these were retained. The highest temperature was 100.8°, the lowest 99°.

The lavage seemed to exercise a very favorable influence over the vomiting; the patient often going over an hour without vomiting. Peptonized milk was put into the stomach by the tube after lavage, and was retained for an hour, when vomiting commenced again. The man slept one hour during the day, but previous to this time had not slept at all. He passed considerable gas per rectum and had two small stools, dark green in color and containing small quantities of fecal matter.

Third day: Hypodermic injections were given of digitalin, gr. 1-100 every four hours, alternating with strychnine; lavage was continued. Peptonized milk, eight ounces, was given by tube. The patient did not vomit for two hours after lavage. The temperature varied between 99° and 100.4°.

On the eighth day, during the absence of the nurse, the patient attempted to sit up and reach a table near the bed. He did not reach the table, but was very much exhausted by his effort, and his pulse which had been between 98 and 100 went to 116 with marked irregularity, and it was a week before it got back to its former condition.

The patient complained considerably of peptonized milk, saying that it made him sick and caused him to vomit. This was treated with sodium bicarbonate, but with very little improvement. He was then ordered malted milk and had no further trouble, and with this was able to take raw eggs daily. The patient was very fond of this, and drank large quantities of it, together with milk and cream, and never seemed to have any further trouble. For several weeks it and its combinations constituted the principal part of his food.

From this time on the patient may be said to have made an uneventful recovery. The Murphy button was found in the rectum on the twenty-fourth day and removed.

During convalescence the patient had days when he would have attacks of sharp pain like colic; these were always relieved by enemata.

His return to solid food was gradual, but when he left the hospital he was eating almost anything he wished.

He had two large abscesses in the abdominal wound during convalescence. One at my first incision and the other at the opening in the median line. They were both large, and evidently due to contact with the gangrenous intestines, which is an illustration of how much more readily sepsis is taken care of by the peritoneum than by other structures; for these abdominal wounds were thoroughly cleansed, and the abscesses were not due to stitches.

The wounds finally closed and the patient left the hospital in first-rate condition. He gained weight steadily after the first three weeks, and when he left the hospital weighed more than when he entered.

He has a slight tendency to diarrhea, having ordinarily one movement a day. His diet is general, but says he avoids eating "too much of green vegetables," thinking they may cause loosening of the bowels. He played golf within two weeks of the time that he left the hospital and now feels as strong as ever. Dr. W. T. Bull of New York saw this case in consultation the second day after the operation, and I am much indebted to him for his advice concerning the after-treatment of the case.

In closing I will give a list of cases, most of which have been published several times: Dr. Charles H. Peck's case, however, has not been reported as yet, but he has kindly allowed me to mention it in my list:

1. Hahn.—32 inches ileum, 8 inches colon, male, thirty-eight years; recovery without disturbance or nutrition.

2. Canthorn (*New York Medical Journal*, 1895) resected 43 inches of small intestines from a man aged forty-nine for sarcoma of mesentery; ends united by Murphy's button. Patient recovered from operation, but died four months later from obstruction brought about by Murphy's button.

3. R. Budberg-Boeninghausen and W. Koch.—Male, sixty-eight years, very robust; 43½ inches; death on third day from peritonitis, which existed at time of operation.

4. R. Budberg-Boeninghausen and W. Koch.—Male; thirty-three years; 43½ inches ileum, for gangrene after incarceration; femoral hernia; recovery.

5. Trombetta.—In 1884 resected 43½ inches of small intestines in a woman aged forty; recovery (quoted by Luggi).

6. Budberg-Boeninghausen and W. Koch.—Male; forty-two years; 44 inches; flexure; gangrene after twisting; recovery.

7. Maston resected 44 inches for sarcoma of mesentery; death five months afterward from perforation due to Murphy's button.

8. Billroth.—Female; fifty-two years; 45 inches small intestines on account of fixation by the extirpation of a fibroma the size of a child's head; death from collapse.

9. Troje.—46 inches; female, twenty-five years; for four ring-like tuberculous strictures; result fistula.

10. Elliott (*Annals of Surgery*, January, 1895) resected 4 feet ⅜ inch small intestines in a man aged twenty-five, for infarction due to thrombosis of superior mesenteric veins; patient was in good health two years afterward.

11. Roux (Sem. Med., 1893) resected 4 feet 1 inch of intestines for a lipoma; recovery.

12. Budberg-Boeninghausen and W. Koch.—

4 feet 1 inch flexure; death from already existing peritonitis on the same day.

13. Budberg-Boeninghausen and W. Koch.—4 feet 1 inch ileum; death on day of operation from already existing peritonitis.

14. Obalinski.—4 feet 2 inches ileum for gangrene; death in twenty-four hours.

15. Studsgard.—4 feet 3 inches jejunum for invagination; death five days after from peritonitis.

16. Schlange.—4 feet 6 inches ileum; gangrene; recovery without disturbance.

17. Braun.—4 feet 7 inches small intestines on account of circumscribed peritonitis; death four months after operation.

18.—Kosinski.—4 feet 9 inches ileum; gangrene from hernia; death from collapse.

19. Muller.—Twelve-year-old boy; 5 feet ileum; cæcum and colon for invagination; death in seven days.

20. Kocher.—5 feet 4 inches ileum; gangrene; recovery without disturbance.

21. Budberg-Boeninghausen and W. Koch.—5 feet 10 inches ileum; cæcum with appendix and ascending colon; artificial anus formed; closed two and a half months afterward; recovery without disturbance.

22. Wullstein.—5 feet 10 inches ileum for strangulation; recovery without disturbance.

23. Schwalbach. —6 feet 1 inch ileum; recovery.

24. Hinterstoisser.—6 feet 4 inches ileum and part of jejunum for incarceration; recovery without disturbance.

25. Schlatter resected, in a man, 6 feet 4 inches ileum for gangrene; recovery with some slight disturbance of digestion.

26. Keoberle.—6 feet 10 inches small intestines for stricture; artificial anus closed after six weeks; recovery without disturbance.

27. Kocher.—6 feet 11 inches for tearing of small intestines; recovery, but subject to diarrhœa if not careful of diet.

28. Dressman.—7 feet 2 inches ileum for gangrene; recovery but slight diarrhœa.

29. Shepherd.—Man, aged twenty-eight; 7 feet 9 inches ileum; after operation thin stools, but increased forty pounds.

30. Harris.—7 feet 10 inches gangrene of intestines, and peritonitis following internal strangulation with perforation; complete recovery.

31. Hayes.—8 feet 4½ inches ileum for laceration of mesentery with crush of intestines; diarrhœa, etc., followed; developed chorea.

32. Peck.—8 feet 5½ inches; rupture of uterus, escape of intestines into pelvis; recovery.

33. Fantino.—Woman aged sixty; 10 feet 4 inches ileum for gangrene from incarceration; recovery.

34. Ruggi.—11 feet; operation for old stricture of intestines; in relieving adhesions mesentery was torn from long length of intestines and resection was necessary.

35. Obalinski.—12 feet 2 inches (practically the entire); death in twenty-two hours.

Another Fire in a Chicago Hospital.—Four hundred patients in the Chicago Home for Incurables were thrown into a panic early in the morning, some days ago, by a blaze that started in the cellar and filled the building with smoke. The nurses and attendants succeeded, however, in quieting the patients, and the firemen quickly extinguished the flames.

MAKING AND CLOSING THE MEDIAN CŒLIOTOMY WOUND.

By AUGUSTIN H. GOELET, M.D.,
NEW YORK.

PROFESSOR OF GYNECOLOGY TO THE NEW YORK SCHOOL OF CLINICAL MEDICINE; GYNECOLOGICAL SURGEON TO THE METROPOLITAN HOSPITAL.

There are two chief results to be desired when a median abdominal incision becomes necessary; first, the avoidance of an unsightly scar; and, second, a strong line of union to preclude the possibility of subsequent hernia.

If the incision is made through the linea alba between the recti muscles, as is the custom, it is not always possible to secure firm, unyielding union of the parts approximated, because of the absence of firm muscular structure in that location. If deep through-and-through sutures are used, including all the structures of the abdominal wall, perfect approximation of the different layers is not secured, and these sutures, by constricting the tissues, cut off the circulation and nutrition (poor, at best, in this location) which is so essential to the healing process. An additional objection to these deep sutures is the occurrence of stitch abscesses, which are not infrequent when they are employed. The buried layer sutures, applied so as to approximate the different layers separately, are much to be preferred, and are objectionable only when they are applied so that space is left between the different layers where blood may collect and interfere with union.

Any form of suture which penetrates the skin is objectionable, because of the cross scarring from cutting of the suture loop, as well as on account of the liability to produce stitch abscesses. The subcuticular suture is the only one free from these objections, but the time required for inserting it properly is a drawback, particularly when the operation has been a lengthy one.

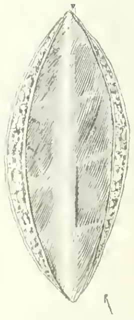


Fig. 1.

Showing incision through the skin and fat down to the linea alba with the margins separated, exposing the recti muscles. The line to the right of the linea alba marks the beginning of the incision of the sheath of the rectus muscle to one side of the median line.

To obviate the foregoing objection, and to secure a firm line of union with the least possible scar, I have adopted the following method of making and closing the median cœliotomy incision, and have employed it with much satisfaction for some time:

The skin and fat are divided in the median line down to the fascia covering the muscles of the abdominal wall; then one side of the wound (right or left, as may be selected for convenience of the work to be done within the abdomen) is retracted, and the fascia covering the rectus muscle, about a third of an inch from the median line, is nicked with the knife and split up and down with the scissors to the limit of the incision in the skin above and below (see Fig. 1). The muscle is then seprated with the fingers in the direction of its fibers down to the subperitoneal fat, which, with the peritoneum, is opened in the usual manner. The advantage thus gained is that in closing the wound muscle is approximated to muscle to one side of the incision in the skin, and a firmer line of union is secured.

In closing the wound, a continuous suture of No. 1 chromicized catgut is applied throughout, and this is tied only at the start and at the finish. The first layer includes the peritoneum, subperitoneal fascia, and the lower border of the muscle on each side, beginning at the upper angle of the wound and continuing to the lower angle (see Fig. 2). By including the lower border of the muscle with the peritoneum in this suture, the leaving of a dead space between the peritoneum and muscle is avoided. Continuing with the same suture from below upward, the fascia is united, and this layer of sutures is made to include the upper part of the muscle with the fascia. Thus, again, a dead space between the muscle and fascia is avoided. The suture is tied off at the upper angle of the wound. Unless the fat is unusually thick, no suture will be required above the fascia. When necessary, it is drawn together by a continuous suture, applied from above downward, the insertions from side to side being made in the direction of the incision and not transversely to it.

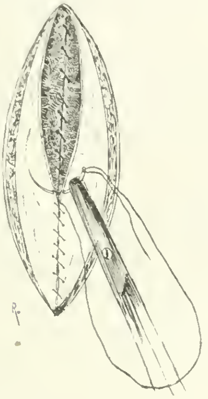

FIG. 2.

Showing the peritoneum and lower margin of the muscle already united by the deeper layer of sutures, and the fascia, with upper margin of the muscle, being closed over it by the second layer of suture.

The margins of the skin may be approximated either by a subcuticular suture or by application of aseptic, adhesive strips, one-quarter inch wide, applied with space between them, to permit drainage into the dressing applied over them. After adjusting loose gauze directly over the strips, a thick pad of absorbent cotton, covered with gauze, is applied over it, and this is held down firmly by means of broad adhesive strips across the abdomen from side to side, securing firm pressure upon the wound.

It is essential that all bleeding shall be arrested before the integument is approximated, and all bleeding points that have been caught with hæmostatic forceps should be ligated with No. 1 plain catgut. Unless this is done, bleeding after the wound is closed may be sufficient to separate the margins of the skin and prevent primary union. This is particularly necessary when the skin is approximated by adhesive strips. Simple oozing is usually arrested by sponging with hot salt solution.

When a second cœliotomy becomes necessary, if the cicatrix is a good, firm one, and [illegible] [illegible] so as to be unsightly, it is not disturbed, but the incision is made a third of an inch to one side through the skin, and so on down through the rectus muscle. If the cicatrix is disfiguring but firm beneath, the skin cicatrix is dissected out, and the abdomen is opened to one side, as has been described above.

In view of the not infrequent occurrence of hernia and disfigurement of the abdomen so frequently encountered as a result of abdominal section, this contribution appears timely.

2030 BROADWAY.

SENSATION AND VOLITION.

By HERMAN GASSER, M.D.,
PLATTEVILLE, WIS.

THE function of the nervous system is divided into two main divisions—an ingoing, or sensory, and an outgoing, or motor function. In this way all the ingoing or peripheral functions of the body are carried by the sensory nerves centrally, or to the brain, where they are adjusted, compared, and equilibrated, and then sent out as organized volitions of life and feeling, in the form of motor nervous energy. This we call the central or motor function of the nervous system. It is only an artificial distinction, however, that has no real existence in fact, for we cannot tell where the sensory side ends, and the motor side begins centrally as well as peripherally; the one shades into the other in the continued circuit of their function.

It is a curious and interesting fact in physiology and psychology that all our sensations are attributed to the sensory or peripheral function of the nervous system, and that we know a great deal about it; while of the motor, active, living, feeling, and ideal side we know very little, comparatively. This is one of the greatest mistakes to which we are all subject. The truth is that the incoming or sensory nervous energy has no psychical existence in fact, until it becomes adjusted into the related unity of life and feeling in the function of the brain, and, when it has reached this stage of its equilibration, is an organized unity of motor expression or volition; and so, in reality, we only know our sensations in our volitions. But the elucidation of the one is a demonstration of the other, for they are parts of the same continued circuit of function.

By the peripheral or terminal function of the nervous system we mean all those reactions that come in immediate contact with the forces of its environment, within and without, that react upon it, and the sensory nerves transmit centrally. The central nervous system is that ganglionic system, of which the brain is its most pure and complete example, the function of which is sensori-motor. It takes up all the multitudinous sensations carried into it, assimilates them into a related unity, and expends its energy in the volitions of life and feeling, which is as continuous in function as the incoming functional energy. And as we cannot have a continuity of function without a physical organization through which it functionates, and no continuity of life or feeling without continuity of a regular and systematic physical organization of the body that binds it into this systematic and related unity, we are forced to the conclusion that the nervous system is not only a physiological but an anatomical circuit in exactly the same sense as the circulation of the blood. Here let us take up the problem of nervous function in detail.

In the muscles, as well as all the internal and external organs of the body, these terminal nerves—centrally and peripherally—spread out in nerve plexuses much as the terminal arteries into the capillaries, are continued on, taken up and connected with the nerves that continue the circuit of the functional nervous energy. It is sensory on the ingoing side and motor on the outgoing, but peripherally, as well as centrally, it is continuous in system. The outgoing or motor nervous energy is elaborated and organized centrally to adjust the local bodily functions into their related unity of life just as the arterial blood carries energy to maintain it, and the surplus is transmitted through these nervous plexuses, plus the local reaction they have caused, and transmitted by the sensory nerves again to the central ganglion in a continued circuit of activity.

We might elaborate this idea with probably greater clearness and accuracy by an analysis of some of the more common special sensory functions, as hearing, taste, smell, or the feelings of pressure, heat and cold because we are more familiar with their physiology and anatomy. They are more common physical entities, and we can follow them with greater ease; but we will take up the physics or physiology of sight, as it is the most involved, specialized, and complex of all the senses with which we are acquainted, for once having even a crude and not wholly complete conception of its function the others will fall into an easy and ready solution.

The optic nerve is really a bundle of about one million nerve fibers, and as it spreads out upon the back and inner side of the eye-ball into what we call the retina, each nerve-fibril terminates in a nerve-cell, and each of the million cells in the retina is intimately connected by the fibrillary plexuses with the others, so that the retina may be conceived as a ganglionic center. As the optic nerve passes inward or toward the brain, each fiber again terminates in a nerve cell in the visual centers, "a place of relay in the optic path," but do not end here, for each of these cells is, anatomically and physiologically, connected with other nerve-cells by these plexuses, forming not only a ganglionic local and special plexelary function, but again to be transmitted to other and more distant parts of the brain, and so on and on, thereby coming into even more intimate relation with all the functions of the body, thus organizing and assimilating them into the related unity of life and feeling with its variations of expression With this anatomical conception, which we must admit is not fully demonstrated, and hence partly schematic, let us follow the physics or physiology of the function of the eye.

If the nerve-cells are really intimately united and connected with one another by these plexuses, then it is probably not so much the cell body proper that reacts upon the forces around them, but that the plexuses perform the true metabolism; that the cell body is, in fact, but a miniature storehouse and special organizer of the plexelary function centrally and peripherally.

This, again, suggests the thought that each nerve cell is an anatomic and physiologic unit, with its special division of labor, and all connected into the general and continued circuit of function, because it is always in a definite direction. This is not the neuron theory, although we have here many points of convergence. The distinction consists of this: the nerve-cells with their dendrites, in our conception are anatomically and physiologically, connected by the plexuses with a regular and continued circuit of function, which the neuron theory denies. Neither of these theories has been demonstrated anatomically, but the evidence from psychology, general physiology, and even anatomy is, to me, so overwhelmingly in favor of the continued circuit and against the intermittent, that I have been forced to believe it to be true.

According to this anatomic-physiological conception of the optic nerve and retina, the particular kind of light or color sensation would depend upon the wave length of the incident light which the specialized cells with their plexuses are specifically organized to react upon and change into nervous energy. This is transmitted along the optic nerve fibers to the brain, where it becomes adjusted or equilibrated, and gives rise to the various color sensations.

It is not the stimulation of the retinal cells and plexuses by the waves of light that causes vision and color sensations, but their reaction upon and assimilation of its energy by transforming it into nervous energy. Simply a feeding of the sense of sight as we feed all the other senses.

While this is not exactly the Young-Helmholtz theory of color sensation, neither that of Hering, though it is more like it than the former, yet it is in harmony with and assimilates the facts in both. It is only a modified interpretation in the light of this idea.

The optic nerve is believed to be exclusively sensory in function, while our idea is that it is motor on one side of the plexuses and sensory on the other side, with a continued circuit of function. This is the most extreme and special test for it, as here the facts and general experience stand in solid breast against it. But if it is true, this special test can be no exception; it must explain or crumble. This makes the problem difficult, indeed, but not necessarily insoluble, and while, for the present, we must relegate it to the realm of not proven—or disproven—as an anatomical and physiological fact, nevertheless our ideal physical conception that the optic nerve is motor as well as sensory in function causes us to believe that it is true here as everywhere else in the organism, and that the future will demonstrate this fact.

The question up for solution is: The optic nerve is motor in function as well as sensory. What is the evidence that causes us to formulate this conclusion? Briefly answered, our general principles of experience, and which here it is possible to portray only in a fragmentary form, as many of the explanations need an explanation for which we have not here the space, neither is it the place.

Physically, or physiologically, it is difficult to conceive how the kind and amount of work performed by the optic nerve and retina can be maintained by the blood alone. The blood nourishes the cells and plexuses, and they react upon it in their characteristic way to maintain their local functional vitality like all the cells of the body generally, but their specific function is to react upon the waves of light and transmit it as nervous energy to the brain, where it becomes known to us as vision, and whereby we may adjust ourselves to a wider range in the unity of nature. When these cells and plexuses are stimulated to increased function, there must be an increased supply of blood to repair the loss of their local functional activity as in all the other organs of the body. The stimulus of the waves of light, like that of the food in the stomach, or the air in the lungs, would cause to be sent increased amounts of motor energy, the prime purpose of which is to stimulate all the locally related physiological functions, of which the blood supply is a part, and so nourish the local functional life. As in the stomach and lungs, so in the eye, there are periods of rest and unconscious activity, but the circuit of their sensory and motor nervous function is continuous; it is only a difference of degree of function. The motor nervous energy sent to an organ stimulates its local vital functional activity which the plexuses react upon, assimilate, and transmit by the sensory nerves centrally, where it becomes known to us as sensation. Hunger is a sensation, the result of denutrition of the body, the whole of which appeals centrally, thus causing its diffuse state of feeling, and thereby stimulating the volitions generally to procure food. Having secured the dinner, the volitions are at once directed to eating it, the reaction of which, in its mastication and digestion, stimulates these special sensations, the local functions of which cause an increased amount of motor energy to be sent to them to maintain the local activity of function in a related equilibrium. It is always an organized and related unity of function, the prime motive of which is the physical economy in continuity.

This is another illustration that it is the plexuses of the nervous system that really perform or adjust and regulate the metabolism of the body, and, as this is continuous, so must also be the function of the nervous system. Here we glean another important lesson, a physiological fact, the value of which has not been generally appreciated: It is not the food in the stomach, the air in the lungs, or the waves of light on the retina that cause the special sensations, but the physicochemical reaction which is taken up by the plexuses and transmitted as nervous energy and sent back as organized motor function. What a wonderful physical parallelism we observe here between the circulation of the blood and the nervous system. The nervous plexuses play the same metabolic and physiological relation and connection to the nervous system as the capillaries to the circulation of the blood. The fact is here also remarkable that the circulation in the blood was demonstrated for a half century before the capillaries were discovered, while in the nervous system the sensory and motor sides of its function have long been known, and even the plexuses demonstrated, and yet no one believes in the circulation in the nervous system. Indeed, in this respect our views are as primitive and confused as they were in the seventeenth century, when Borelli and Willis believed it to be a "nervous fluid, possessed of peculiar properties, a kind of foreshadowing of an electric fluid." Foster. That which circulates in the nervous system is not a fluid, neither is it electricity, but a specific and specialized form of nervous energy, the result of the biochemical functions of the body. This is also why it is not in all its parts alike, and we have "the specific energies of the nervous system" of Johannes Mueller. Nervous energy, like light, heat, and electricity, is a form of force, and hence the last and ultimate reduction of its phenomena. It is here we find the delusion and snare of the "new physiology" in its endeavors to build up an electro-dynamic theory of life.

If the waves of light reacted upon the retina generally and diffusely, we would have a very diffuse idea of the relation of things with one another of the outside world. There would be no clear, distinct, and specific entities, because light travels in a straight direction. But we have lenses and media through which the waves of light of the outside world pass, and so converge them as miniature facsimiles upon it, thus giving the special object a definite and well-defined existence, a clear and distinct image of the related outside world. It is not the photographic miniature image of the outside that we really see, or that passes into the brain, but its reaction upon the retina as related waves or forces of nervous energy as they are adjusted or equilibrated in the unity of related function in our feeling. Indeed, it is not with the eyes we see but through them by assimilating their special physicochemical reactions into the related unit of life with its variations, the measure of which is interpreted in our feelings.

It is fully as important physically, that the anatomical and physiological activity of the cornea, lens and humors be intact, as the retina and optic nerve. While we think we fully understand the physics of optics, yet the physiology of these simple lenses is equally as wonderful. Indeed, as a fact of organized and adjusted physics in the constructive unity of nature, it is so transcendent that we are overwhelmed by it. In the physical architecture of the eye alone is written large that nature is an idea; a constructive, creative development; an evolution of which we are a related part.

Here we are confronted by another physiopsychologic fact. Why then do we not have pain when the optic nerve is cut, the same as we have in nearly every other organ of the body? In biology, as in chemistry, there is a system of organized and related affinity, and if it departs too much from it there is no reaction. The function of the optic nerve and retina is purely confined to react upon waves of light, and if diseased or injured can only be stimulated by them, and so cause pain. It does no react functionally or physicochemically upon the forces like cutting and trauma, and hence cannot transmit it centrally. But destruction of any of its parts in continuity means a loss of sight, and so indirectly causes a painful state of feeling, for it is, anatomically and physiologically, connected with the entire unity of function.

But why pain, then, in all the parts of the body when their nerves and plexuses are cut or injured? Here the trauma is also a part of the organ, upon which they react and around which they still continue to functionate with increased activity, and hence painful. Those organs, when removed completely under anæsthesia, cease to functionate, and are not painful when consciousness returns, but the nerves and plexuses around them are felt because still intact. This explains all the phenomena we observe after an operation.

We may shave away the cortical portion of the brain without pain, and have a living automaton without painful or conscious feeling of any kind, and yet this automaton still feels, reacts upon, and responds to, special sensory stimuli regularly and systematically, but it is the organized, instructive, and established feeling that is unconscious, because no longer interpreted into a related unity of the whole in the cortical brain.

With this idea of the physiological function of the nervous system, we are justified in stating that the brain is a related, systematic, anatomical, and physiological ganglion, composed of fibers and cells, with a definite circuit of function, although a large part of its more intricate and delicate connections still remain obscure. The brain is more complex and involved in its constructive architecture, because it is organized and developed to adjust or assimilate all the variations of functions or sensations that come into it. These may be conscious and unconscious; the difference is one of degree or tensity of activity. To illustrate:

Sharp and distinct vibrations of air impinge upon my auditory nerves, are carried to the brain, and from experience I know it is an alarm of fire. In an instant they have traveled the entire circuit of nervous functions and caused a definite and specific reaction. Sharp and distinct vibrations impinge upon my ear and are adjusted in the brain, but I do not hear them; it is the tick of the clock. The clock ticks, the fire-bell rings, it rains, the wind blows, and yet you do not know it; your sleep is too deep, the stimuli do not react with sufficient intensity to cause them to rise into states of consciousness. In all these instances it is an organized reaction in continuity of function, the prime purpose of which is its economy of adjustment to the environment—the law of self-preservation. It is purely a matter of organic physics along the lines of least resistance, or organized continuity of function.

The living body is a constructive machine that is continually adjusting itself to the forces of nature. It is not only constantly assimilating energy, but, volitionally, giving it off to maintain its relation in it. The terminal plexuses are the receivers—in other words, they react upon the forces of nature, which the sensory nerves carry centrally, where this varied form of nervous energy becomes not only adjusted, but which nutrition builds up and organizes to systematically expend by volitions. The incoming energy is the raw material, the central ganglionic plexuses, the factory and the volitions, the finished product, but all related parts of the organized unity and continuity of life.

Let us illustrate this idea of organic physics by examples of inorganic physics with which we are familiar, for if nature is a unity, subject to the same laws, there must be an intimate relation between them. Lately I had the pleasure, with many others, of being entertained by a phonograph. It caused great pleasure, merriment, and applause. The feelings were stirred into ideal states. On examination of the instrument we could find only a hard rubber cylinder with fine and irregular streaks, but nothing like a song or speech, and yet the energy put into the instrument by winding the spring caused their production. This, surely, is purely physical. No one doubts that the song, or speech, was transmitted to it by some human being; but in the machine it is pure physics. This, we know, is the result of vibrations of air on the wax cylinders as they are impressed upon it with their variations of relation systematically, and reproduced by unfolding them in the same way that they were received.

Waves of light, as well as air, may also be definitely and accurately recorded, so that one can not only hear the opera, but see the actors upon the stage going through the performance. It is a purely physical phenomenon. The telegrapher strikes the the key at one end, the energy is transmitted by the wire to the other, and reproduced. In the telephone, instead of striking with the fingers, we strike with modulated waves of air, in the form of words, which are transmitted along the wire in their varying wave lengths and reproduced again in speech. It is all mechanical physics, yet behind it, after all, is the organized genius of man, who builds and creates these machines. But this is possible only because he is also a machine, governed and controlled by the same physical laws. Long before we had such demonstrative evidence of the mechanism of nature, the great and immortal French philosopher, Descartes, clearly elucidated the idea that man is a machine, and which these modern experiences only make more systematic and complete.

From this series of experimental physical facts, the thought suggests itself that the organism is not only a receiver and constructive organizer, but transmitter of the forces or energy of nature; and that the great problem is: how are these functions performed? General experience demonstrates that we do not have a picture of the man, house, or tree in us, but a related system of their forces in function, as they react upon us and are adjusted into the unity of life and feeling. Man being a machine in the machine, the thought again suggests itself that it is the plexuses—peripheral and central—that perform the real work of equilibration and adjustments; that the physical forces react upon the peripheral plexuses, the energy of which is transmitted by the sensory nerves to the central plexuses, where it is again reproduced, adjusted, and organized by nutrition as a memory, and expended in the form of volitions. In this way the specialized central plexuses in the brain become organized along definite lines by continued repetition as physical functional memories, as in the cylinder of the phonograph, and may be repeated, or reproduced in the form of words, a song, or an oration along the organized system of their experience or physical memory, but always as a related unity of its organized and constructive existence.

While we have compared the function of the nervous system and brain with a phonograph, physically, yet the distinction between them is as infinity to one. The latter is only a simple machine, in which a few vibrations of air have been systematically recorded, while into the brain there are poured millions of sensations constantly and continually, and all assimilated and equilibrated with the countless millions that have gone before into a related unity of life, mind, or feeling that is continuous, although it has its ebbs and flows, as sleep at night, and ideal conscious feelings during the day. It is only a difference of degree.

While the wax cylinder takes up the impressions of the song or speech with the accuracy and system poured upon it, the brain cells are much more plastic and impressionable—indeed, so delicate, that if vibrations could be transmitted to them with the intensity and volume with which they are poured into the phonograph, it would cause immediate disintegrations and death. The special forces or sensations that we hear and see, and feel, are so attenuated and modified in volume and intensity, as measured by the energy that gave them being, that they are only an atom, taken up out of the energy of nature, and yet an accurate measure of the whole. This is why man is a finite, creative unity, woven out of the Infinite Creative Unity. A finite idea of the Infinite Idea.

This is the physics, the science, the harp that weaves the varied sensations into ideas; not their psychology, much less their philosophy; but as they are interdependent and related problems of the same unity of nature, an elucidation of the former will have a directive, purposive, and systematic effect upon the latter, thus building them into increasing splendor and beauty. It should always be remembered, and never forgotten, that system is not solution.

A French Veterinarian on the Koch-Garnault War.—M. Nocard of the Alfort Veterinary School said recently, in an interview in the *Figaro*, that Garnault's experiment of inoculating himself with bovine tuberculosis was useless and unconvincing, since Koch's contention had to do with the transmission of tuberculosis by the ingestion of infected meat and milk and not by inoculation. Garnault, he said, should have confined himself to drinking the milk and eating the flesh of tuberculous animals. He expressed himself, however, as wholly opposed to Koch, for he believed the disease was practically the same whether in man or bovis. Speaking of Koch's sensational paper, read before the London Congress, Nocard pointed out that statements had been of great use to the German Government in the agrarian question, and he wondered whether Koch had not been subjected to influence from high quarters.

THE GLYCEROPHOSPHATES;

PARTICULARLY THE GLYCEROPHOSPHATE OF SODIUM.[*]

By P. W. STREET, M.D.,
SUFFIELD, CONN.

In 1894 Dr. Albert Robin presented to the Academy of Medicine of Paris a report upon the results of his employment of the glycerophosphates of calcium, potassium, and sodium, which he had been using in his practice, at that time, for six years. Noted as an observer, his conclusion that these are valuable agents in the treatment of nervous debility from various causes attracted wide attention. Soon afterward, both in France and America, other physicians of prominence began to utilize the information he at that time imparted, and, later, with striking unanimity, corroborated his results.

An investigation of the subject reveals an absolute lack of information at the usual sources, and the information as yet obtainable is found only in contributions to medical periodicals.

Known to exist, and regarded as likely to possess important therapeutic value, the glycerophosphates were not put to therapeutic uses for many years because of the inability to produce them upon an industrial scale.

Derivation.—They are products of the action of glycerophosphoric acid upon various bases. Glycerophosphoric, or glycerinophosphoric, or phosphoglycerinic acid ($H_2 PO_4 C_3 H_5 (OH)_2 + aq$), is said to be a yellowish, oily, odorless liquid, soluble in water or alcohol, and obtained from glycerin and phosphoric acid. It is also a product formed in the human body during digestion.

The glycerophosphate of calcium, at first most extensively employed, is a white crystalline powder, soluble in 20 parts cold water, sparingly soluble in hot water or alcohol. Dose 10 to 20 grs., given in capsule, powder, syrup, or watery solution.

The glycerophosphates of iron, lithium, and magnesium, as sold, are fine white powders, soluble in water. They are given in doses of 3 to 20 grs. t. i. d.

The glycerophosphate of quinine, also a white powder, is bitter in taste, and sparingly soluble in water, but more soluble in alcohol. It contains 68 per cent. quinine. Dose 3 to 6 grs.

The glycerophosphates of sodium, and of potassium, are each very hygroscopic, and are sold only in a 75 per cent. solution in water. In this form they are saline in taste, jelly-like in appearance, and affected in their consistency by changes in temperature. Dose, 10 to 30 grs. t. i. d. in syrup, or watery solution, when taken by the mouth, and 5 to 10 grs. when given hypodermically.

The glycerophosphate of sodium is the salt which has latterly received the most attention. It is used in this country, according to the statement of the manufacturers, twice as extensively as the calcium salt, which is next in importance.

Physiological Action.—The glycerophosphates supply phosphorus to the tissues in an easily assimilable form, an organic phosphorus. And, since phosphorus is a most important constituent of those cells which comprise the brain and nerve substance, their utility as a nerve food or tonic is naturally suggested. Lecithin, the phosphorus-bearing substance found in all the cells, and especially the nerve-cells, is itself the glycerophosphate of neurin.

The action of mineral phosphorus is thought to be exerted by it, causing molecular irritation. This results in temporary stimulation, but tends toward waste, and impoverishment, rather than increased nutrition, of the cells.

The hypophosphites, so often prescribed in debilitated nervous conditions, are said by Hare to have no advantage over phosphorus, except in case of administration; and Ringer states that their mode of action resembles that of phosphorus.

The comparative value of a remedy which simply and directly promotes the nutrition of the cells is obvious.

Taken by the mouth the glycerophosphate of sodium is perfectly tolerated by even the most delicate stomach. It has no immediate effect that is noticeable; but when its administration has been sufficiently prolonged, the appetite improves, assimilation and absorption are promoted, the liver is stimulated, the flow of bile is increased, nitrogenous exchange is hastened, and phosphatic waste restrained.

Acting upon the nervous system existing reflex nervous phenomena usually diminish and finally disappear; sleep, if disturbed, becomes more quiet and restful; and insomnia often disappears without other aid. Large doses (30 to 60 grs.), however, may cause wakefulness.

The various organs and tissues of the body all show improved functional activity. The eyes grow brighter and clearer, and the complexion more healthy. Thin and nervous subjects gain flesh, and flabby flesh becomes more firm.

It is noticeable that there is no reaction after the withdrawal of the drug, either after short or prolonged administration. The patient continues much as before, retaining the improvement made. And the progress of improvement is resumed, upon a return to its use. These effects are also largely true of the action of the calcium and potassium salts.

Therapeutic Uses.—As I remarked before, there is great unanimity in the verdict of those who have given the glycerophosphates an extended trial, as to their effect and therapeutic value. In the employment of sodium glycerophosphate, hypodermically and by the mouth, in twenty-five successive cases, I distinctly observed the following facts which, upon research, I found substantiated the statements made generally by contributors upon the subject:

The glycerophosphates are indicated, and most useful, in all cases of nervous impairment due to overwork, or excesses of any kind. Also in asthenic nervous maladies, mental depression, and whenever it is desired to increase the nutrition of the nerve-cells, and stimulate their activity.

In neurasthenic conditions characterized by vertigo, occipital headache, unsteadiness of gait, or inability for physical or mental effort, great improvement attends their use. In the premature advance of age, and in senility, attended by general debility, the benefits from their protracted use are striking. They greatly relieve hysteria, and also the many morbid feelings of nervous patients. Their value is considerable in chronic neuralgia, in sciatica (by hypodermic injection along the nerve), and in convalescence from la grippe, and acute infectious diseases.

In diabetes, Magnin of Paris asserts that he has personally seen, repeatedly, the sugar markedly diminished by them. And they are said to be useful in Addison's disease.

Contraindications.—Their use is contraindicated in albuminuria; in diseases characterized by an organic oxidation in excess, as acute gout, or acute rheumatism; and especially in nervous states characterized by acute excitability.

Incompatibles.—The glycerophosphates are liable to undergo decomposition when brought into contact with lead salts, phosphates, or carbonates.

---

[*] Read before the Connecticut State Medical Society, in May, 1902.

Administration.—The effects of the glycerophosphates are most quickly secured, and most pronounced when administered by hypodermic injection. The solution usually employed consists of

℞	Glycerophosphate of sodium	12 grs.
	Sodium chloride	½ gr.
	Distilled water	1 drachm.

M Sig.: 15 to 30 minims injected once daily (with antiseptic precautions).

As watery solutions are a good culture medium, they should be kept sterile, or freshly prepared, when for hypodermic use. The best site for the injections is the back. The injection is apt to be followed by stinging pain of moderate severity, persisting for several minutes; also soreness, and redness lasting several days.

I regard the incidental discomfort of the hypodermic method so objectionable, in many cases, as to render the use of it but seldom desirable, or to be employed but for a short time at the outset of the treatment, as in a case where it is necessary to secure an immediate response. Sufficient doses given by the mouth are equally satisfactory.

The glycerophosphate of sodium is taken agreeably in either the syrup of orange or the compound syrup of sarsaparilla, 10 to 30 grs. to the drachm. It should be administered three times daily, either before or after meals.

The following also is an effective formula:

℞	Glycerophosphate of Sodium	7½ grs.
	Glycerophosphate of Quinine.......	1 gr.
	Glycerophosphate of Iron..........	2 grs.
	Glycerin	1 drachm.

Citric acid q. s. (to complete solubility).

M. Sig.: To be taken in water before each meal.

To secure the best results, it is usually necessary to administer the glycerophosphates for from three to six months, and sometimes longer. Occasional interruptions of several weeks in the course of very prolonged administration are beneficial. In such cases, too, the giving of strychnine and appropriate hygiene are desirable auxiliary measures of treatment. While excesses of any kind, and the use of tea, coffee, tobacco, and alcoholic liquors are to be avoided. It is also well to vary the vehicle, that the patient may not tire from the monotony of the treatment.

The Treatment of Enuresis.—Karl Walko considers that the ordinary enuresis of children is, in most cases, a neurosis, depending on the psychical inhibition of a normal organ, and does not involve either faulty development or muscular weakness The instances in which the condition is symptomatic of other lesions are fewer than is generally supposed, and the success that often follows the employment of such measures as the removal of adenoids from the pharynx is to be ascribed purely to the influence of suggestion, as are also the good results of blistering the nape of the neck cauterizing the lumbar region, etc. Internal medication for this affection is falling more and more into disrepute, and in his hands the most efficacious plan of treatment has been massage, or vibratory, rectal, or the combined rectal massage as recommended by Thure-Brandt for the bladder. This is carried out as follows: The patient is placed in the dorsal or knee-elbow positions, and one hand just over the symphysis is pressed against the forefinger of the other one in the rectum. With the latter the neck of the bladder is subjected to gentle circular or transverse massage movements for periods of from four to five minutes. Functional enuresis was permanently cured in this way in, on the average, three to five sessions, and even symptomatic cases were frequently benefited —*Zeitschrift fur diätetische und physikalische Therapie.*

MALARIAL INFECTION A POTENT FACTOR IN ASTHENOPIC CONDITIONS.*

By J. LAWTON HIERS, M.D.,
SAVANNAH, GA.

Since the publication of my paper on "Malaria as an Etiological Factor in Asthenopia," in 1898, medical literature has not been appreciably enriched by contributions of similar import. Innumerable subjects within the province of the ophthalmologist have been aired and ventilated before distinguished gatherings; and yet virtually little has been said concerning an infection which must needs of necessity have attracted the attention of not a few of our most astute thinkers and clinicians. It is in the hope, therefore, of elucidating the relationship between malaria and asthenopia that the author has presumed to revise his article read, two years ago, under a kindred caption.

It is, furthermore, his purpose to discuss a few practical points connected with this trouble, in which, through the instrumentality of the microscope, malarial plasmodia have been demonstrated in abundance, and on account of which an anti-malarial treatment has invariably proven beneficial.

The term "asthenopia," like many other medical words, is convenient and decidedly ambiguous. From a diagnostic standpoint it is incomplete, and signifies practically nothing. It must be coupled with an adjective to qualify or convey its meaning; for existing alone no true conception can be formed as to the pathology of the affection of which a patient may complain.

Lexicographers define the word as "weakness of sight, accompanied by fatigue, strain, indistinctness, dread of light," etc., and most writers have recognized an anatomical or physiological abnormality as the chief etiological factor, hence the symptomatic designations—accommodative, muscular, intraocular, or nervous asthenopia. Of the several groups, the first comprises the greatest number of cases—for the alleviation of which condition, in most instances, nothing is required save the proper adjustment of glasses. The second classification, while comparatively rarer than the first, includes many of the most intractable cases of asthenopia; and these, in the event that prisms have proven of no avail, should be subjected to surgical interference. Concerning the third and fourth subdivisions there is much that can and should be said, for some writers attribute all cases of weakened vision to ametropia or heterophoria; and it is especially in opposition to this view that this article has been prepared.

In intraocular or nervous asthenopia let us consider malarial infection as a potent factor. The microscope will substantiate this position, and while it is not my desire to be classed with those physicians who hold malaria culpable for every ailment of the human family, yet the fact is incontrovertibly established that many diseased conditions result from malarial poisoning without the manifestation of a febrile reaction. Illustrative of such may be mentioned hæmoglobinuria, enlargement of the spleen, malarial neuralgia, motor ocular paralysis, etc., and if the contention be granted that it can and does affect the liver, spleen, kidneys, and nervous system, the argument that it, likewise, assails the eye and is responsible, in a measure, for given conditions, is both possible and rational.

To theorize is to acknowledge skepticism, and skepticism invites infidelity. Man must have a belief to be earnest. Sincerity implies truthfulness; and truth must be demonstrated. It can only be accepted when facts are practical and unbiased; when experience, and not conjecture, is corroborative. Appreciating this, without further transgressing the domain of metaphysics, and apologizing for having indulged this illustrative digression, let me present, in evidence, the following cases: Early in July, 1896, Miss N., eighteen years of age, presented herself for treatment. Family history good, physical condition rather robust, and health otherwise apparently perfect. About the middle of the previous winter, while at college, her eyes became so weak and painful that she was forced to leave and consult a physician. During the interim, prior to visiting my office, she had consulted two reputable oculists, from whom she claimed to have received only temporary benefit. An examination revealed clear media, and an otherwise healthy fundus. The external muscles and appendages were normal, save a mild form of catarrhal conjunctivitis, which promptly yielded to medication. Her refraction proved, that although able to read 20-15 with either eye with ease, yet it could be held only for a few moments. After two examinations Lens 25D. cly, ax 90 was prescribed for each eye. This afforded some, but only temporary, relief, and forced me to the conclusion that there were present other than the usual causes of asthenopia. Having watched and studied the case for several days, there became apparent a decided periodicity in her asthenopic paroxysms. Further questioning divulged the fact that, although never a victim of fever, she was reared and had lived at all times in a malarial district. A specimen of blood having been obtained and examined microscopically, the presence of hæmatozoa was readily determined. Liberal doses of quinine bisulphate and arsenous acid were given in combination. After three days of treatment the pain and weakness of vision had disappeared, proving conclusively that malarial poisoning had occasioned her indisposition. To eradicate the same thoroughly from her system the treatment was continued for several weeks. The subsequent fall she was again able to resume her studies, and, at this writing, has not had the slightest indication of any further inconvenience or trouble.

---

*Read before the Pan-American Medical Congress at Havana.

The second case is given in greater detail than the preceding on account of its peculiar interest. It is purely of malarial origin. James E., a negro, twenty-eight years of age, a native West Indian, but for five years or more a resident of this country, and by occupation a hotel waiter, sought treatment December 3, 1897. An intense eye pain and weaksightedness occasioned his visit. An examination confirmed the existence of an acute catarrhal conjunctivitis, to which was referred the condition above noted. The usual treatment was adopted and dark glasses recommended. At the expiration of the third day the conjunctival inflammation had entirely subsided, but the patient claimed to realize no appreciable improvement.

An ophthalmoscopic examination of the eye resulted negatively, while his refraction and the external muscles indicated no abnormality. Microscopically, the blood abounded in malarial plasmodia. Almost every cell was impregnated with hæmatozoa.

Except for a slightly torpid liver, which was promptly relieved by a mercurial purge, his physical condition and general health were excellent. At no time could a rise in temperature be detected. His history evidenced the fact, however, that two years previous, when visiting the West Indies, he had had an attack of intermittent fever of fourteen days' duration. Consequently, large doses of quinine, arsenic, and strychnine were prescribed, and in two days there was a slight change for the better. Within three days his condition had been perceptibly ameliorated. The anti-malarial treatment was continued, and in the afternoon of the eighth day after the beginning thereof absolute relief had been obtained No difficulty was experienced in using his eyes, and even in a very bright light he suffered no inconvenience. Nevertheless, to guard against a possible recurrence, the same medication was advocated and advised for a further period of ten days Since then he has been seen twice, and no renewal of his trouble has been noted, even under the most adverse circumstances.

Since July, 1896, it has been my good fortune to observe and treat sixty-eight patients with asthenopia, of whom twenty-eight were males and forty female. Of these cases, thirteen in males and nineteen in females were accommodative in character and entirely relieved by the proper adjustment of glasses. Nine males and eleven females were hypermetropic and had associated malaria. They were fitted with glasses, but without permanent relief until placed on an anti-malarial treatment. Eleven cases, seven male and four female, were purely of malarial origin. One male with insufficiency of right internal rectus muscle and normal refraction, but whose blood abounded in plasmodia, was permanently cured by the administration of strychnine, arsenic, and quinine. The condition of one male with insufficiency of the left internal rectus, after a futile trial with prisms, was alleviated only by tenotomy. Two cases in females were traced to uterine reflexes, and the patients were referred to their family physicians. One case of neurasthenic origin was assigned accordingly. The blood of one female, presenting insufficiency of right internal rectus, and hypermetropia, contained hæmatozoa.

Thus, to summarize, twenty cases of hypermetropic asthenopia associated with malaria, as proven by the microscope, have come under my observation during the past four years. In addition there have been eleven with no other assignable cause. Parasites in abundance were observed in each blood specimen examined: and an anti-malarial treatment, when indicated, verified the contention that this malady is an etiological factor in the production of certain well-defined asthenopic conditions.

From the evidence produced the following conclusions are deducted: (1) That two distinct forms of malarial asthenopia exist—acute and chronic. The former is seen most frequently by the family physician, and is characterized by the eye strain, pain, and weakness of vision which accompany febrile reactions of an intermittent or remittent type. The latter more frequently falls under the care of an oculist, and may be associated with muscular or accommodative asthenopia, or both. (2) That asthenopia *per se* does not exist, but must possess some qualifying cause. (3) That the interocular and neurotic manifestations should be classified individually and not generalized. (4) That microscopic investigation can and does determine the prevalence of plasmodia in certain of the aforesaid conditions. (5) That a febrile reaction does not of necessity accompany the history of the case. (6) That under judicious anti-malarial treatment, provided the presence of hæmatozoa has been demonstrated, the causative factor can be readily eradicated and a permanent cure affected.

Lunacy in Edinburgh.—There has been a large increase in the lunacy rate in the Edinburgh district within recent years, and, as a consequence, the accommodation for the insane has become completely exhausted

It is announced that the total number of pauper lunatics belonging to the district had increased from 512 in 1898 to 704 at the beginning of this year —*London Times.*

THE USE OF ARGYROL IN THE TREATMENT OF ACUTE GONORRHŒA.

G. K SWINBURNE, M.D
NEW YORK.
SURGEON TO GOOD SAMARITAN DISPENSARY.

That the treatment of acute gonorrhœa has been much improved since the introduction in recent years of the series of new silver preparations is well recognized by the majority of those who have had experience with them.

The qualities sought for in their manufacture was the production of a preparation which while capable of destroying the gonococcus is at the same time unirritating to the delicate mucous membrane of the urethra. Further, it should possess the power of penetrating the living tissue, in order to reach the germs which are multiplying in the deeper layers, without causing the slightest damage to these tissues. These preparations, which are made by combining silver with some form of albuminous product, possess two noteworthy qualities: They do not coagulate albumin, nor is silver chloride thrown down when they are brought in contact with a solution containing sodium chloride. As to the penetrating power of these compounds when in contact with living tissues it is impossible to make a satisfactory proof, though experiments have been made to test their power of penetrating dead tissue.

Argonin, protargol, and albargin are the best known of these products, and deservedly the most popular. Argonin contained only about 4 per cent. of silver, but when used in 10 per cent. strength, which is the limit of its solubility, is, in my experience, absolutely unirritating and very satisfactory. It was, however, rather troublesome to make up the solutions, which deteriorated after a few days, and so was replaced by protargol, solutions of which were much more easily made, kept longer, and were more convenient to use. Protargol contains about 8 per cent. of silver, but cannot be used in the urethra in solutions stronger than 1 or 2 per cent. In this strength it certainly caused pain in some cases, so that, until the patient became accustomed to it, its use had to be supplemented by the injection of a solution of cocaine. When used in the deep urethra there were many cases in which it would cause marked discomfort, lasting as long as an hour. Nevertheless protargol has proved to be of very great value, and will undoubtedly retain its place for some time. Albargin, containing 15 per cent. of silver, has more recently been brought to the notice of the profession, but, in my experience, while in some cases it could be used with good results in strength of from ½ to 2 per cent., in other cases, even in the strength of ½ per cent., its use had to be abandoned because of the discomfort produced. It is readily soluble, the color of the solution being a very light yellow, and apparently it did not stain the patient's linen.

In March of the present year, A. C. Barnes, M.D., of Philadelphia called my attention to a new silver preparation manufactured by himself, to which the name argyrol has been given, and asked me if I would try it on a few patients, which I readily agreed to do. This preparation is not a patented article. For its chemical properties the reader is referred to Dr. Barnes's article in the Medical Record of May 24, 1902. It comes in dark-brown scales, is very hygroscopic, and is soluble to almost any degree in water. The solutions keep well without deteriorating. It contains nearly 30 per cent. of silver. It possesses one drawback, which everyone who uses it will be very apt to note, and that is its staining properties. On account of this it has to be very carefully used, for though, when properly treated, the stains are readily removed, yet it is distinctly disagreeable to the patient to get it on his underwear. Boiling water removes the stains; they can be readily washed out when fresh. After the stains have become dry, I have found it better to moisten the spots with a saturated solution of iodide of potassium, after which they readily wash out. Stains of the hands are easily removed with soap and water.

From March 6 to August 1 upward of 350 patients having a gonococcus-bearing discharge were treated with this drug, at the dispensary. Cases at all stages of the disease were studied, but the great majority of the cases were acute. Full records of these cases were kept after the manner described by me in previous papers, and have been tabulated, but, as the method employed is not what I consider the best way to use this remedy, I do not think it of as much value to take up space with them as it would be to describe the methods which I have finally come to employ in my private work.

In the beginning all the patients thus treated at the dispensary were given a single daily injection of 2½ to 3 drachms of a 1 per cent. solution, which was held by the patient for 10 minutes in the anterior urethra. Cases in which the posterior urethra was involved received in addition a deep instillation of an ounce of the solution through a small flexible catheter, which was then urinated out.

In this work I did not, except in a few cases that could not come daily, give the solution to the patient to use at home, as it has been my habit and practice for a number of years not to do so.

In going over the records I noted that many patients doing well would drop out for several days, then reappear with renewed discharge, again attend till they were doing well, again drop out. It was easy to see the reason: they were comfortable; they had no discharge; they thought they were well, and so remained away until the reappearance of symptoms. Under this see-saw arrangement the disease would gradually travel down the canal until the posterior urethra became involved, and consequently the usual complications would be found in some of these cases, and we had our due proportion of prostatitis, epididymitis, etc. But, on the other hand, we had also our due proportion of cases who came faithfully and regularly, who recovered completely in a moderately short time, successfully passed through their "beer test," and, to all appearance, as thoroughly cured as our present methods of investigation permit us to judge.

After these injections there was absolutely no reaction and no pain. After three months of use at the dispensary, I gradually began to use the drug in my private work—this since the latter part of May—until the past month or more I have used almost nothing else. I have used it by irrigation, in strength of from 1-2,000 up to 1-500, using 1 quart at a time, and there is hardly any difference to be noted in the reaction following either strength. I have followed this by injection of from 1 to 5 per cent. into the anterior and posterior urethra without any reaction whatever. Old patients, who have been repeatedly irrigated with permanganate and other solutions, have often remarked upon the comfort following their treatment by this drug, and the results have been as good as, I believe, they can be, with this tormenting disease.

In treating patients I use several methods, according to different circumstances, such as the severity of the disease, the chance of aborting the disease, and the patient's ability to come frequently or not. Treatment may be daily. In such cases I irrigate the urethra with one quart of hot 1-1,000 or 1-2,000 solution of argyrol, follow this by a 2 or 5 per cent. injection or installation, as the case demands, and have the patient use a 2 per cent. solution of argyrol at home once or twice a day in addition, or it may be no injections are used by the patient at home.

Some patients may only be able to come once or twice a week—they get the same treatment when they come to the office, and use a 2 per cent. solution two or three times a day at home.

I use argyrol for irrigation before the use of urethral instruments where I before used permanganate solutions.

In chronic cases I have seen good results by the use of this drug. Cases needing sounds get now, as a lubricant, on the sound, a 5 per cent. ointment made with adeps lanæ as a base, the argyrol being rubbed up with water just enough to render it smooth before incorporating it with the ointment.

I cannot help laying great stress on the painlessness of the drug. I have frequently dropped a 10 per cent. solution into my own eye. Any one who knows the sensation produced by 2 per cent. protargol on the eye will readily appreciate the difference. The argyrol hardly produces a sense of warmth.

During the past week I have used at the dispensary as strong as 20 per cent. in three cases of primary gonorrhœa of twenty-four hours to three days' duration without producing any pain to the patient, one patient saying the following day that he had experienced no discomfort either from the injection or the disease since the treatment of the previous day. These cases are cited only to show the painlessness of the drug. It has been so used too short a time in this strength to know its value thus used as a curative agent.

Of all the cases thus treated only one case showed a peculiar idiosyncrasy, which began after the patient had been treated for two weeks. That was great pain in the urethra after injection, lasting perhaps an hour or more, and the injection of cocaine afterward in this case did not give relief.

To sum up, this drug has decided gonococcidal powers; it has a decided effect in reducing and allaying inflammation of the disease; it can be used safely in almost any strength and at any stage of the disease; the injection can be repeated almost as frequently as the fancy of the physician dictates; I have not seen any unpleasant symptoms due to the use of the drug, and I believe it to be one of the most valuable remedies given to the profession in recent years.

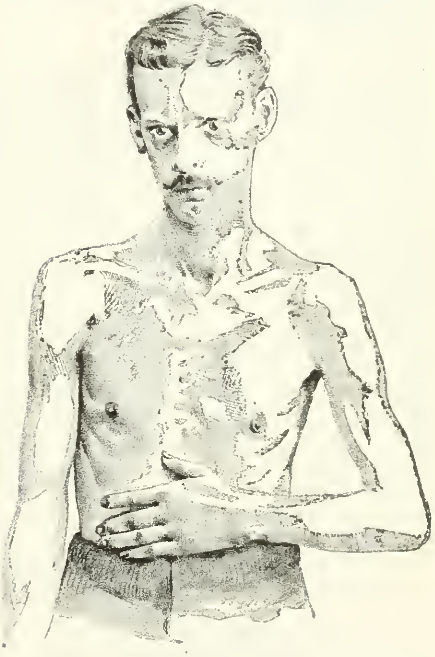
I cannot help reiterating here, as it is so often lost sight of in reporting cases, that it is important to remember that there is a great difference between a primary attack and multiple attacks of gonorrhœa, and the real test of a drug in an acute gonorrhœa is its behavior in primary cases.

Bacteria in Low Temperatures.—The researches of Professor Dewar at the Royal Institution of London on low temperatures show that all bacteria are not destroyed, even at the lowest. Certain species live when subjected for days together to temperatures as low as 310° F. The phosphorescent organisms cease to be luminous at the temperature of liquid air, but the chemical reactions producing the phosphorescence are only suspended, for the luminosity recurs when the temperature is raised. It cannot longer be assumed, then, that the temperature of space is sufficient to destroy all life, and it is not absurd to suppose that life can be transferred from one planet to another. If the bacteria will only choose cold meteorites they have a chance for life. But they must avoid the red-hot surfaces of such celestial carriers.—*The Sun*

A CASE OF RAYNAUD'S DISEASE OCCURRING IN A PATIENT SUFFERING FROM GRAVES' DISEASE.*

By S. W. THOMPSON, M.D.,
OSWEGO, N. Y.

L. J., male, twenty-nine years old, native of the United States, came from a family of neurasthenics. There was a history of specific trouble, manifesting itself in the nervous system in members of this mother's family. The patient was always extremely nervous as a child. He occasionally had fainting fits, and when in school, if teased by other boys, would throw himself into a convulsion, apparently at will. Nine years ago he became a sufferer from Graves' disease. The goiter and exophthalmos were well marked, the pulse was rapid, and the breathing was affected at times. In the autumn of 1901 he had a severe attack of typhoid fever, recovering in November. In December he noticed that the middle and ring fingers of his left hand became cold and pale when exposed to the air, although it was not extremely cold weather. This condition grew worse, and pains began to dart through his arm and into the hand. Thinking that it was only neuralgia and would get well, he did not consult a physician.



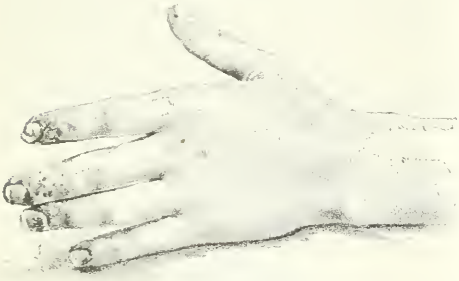
In April, 1902, he was putting up a barbed-wire fence and scratched the palm with a piece of wire. Although it was not a severe wound, the pain in his hand increased in severity, and then, thinking that he was a victim of blood poisoning, he consulted a doctor. There was no septic condition, the wound healed as any scratch would, and the patient was told that he was suffering from neuritis.

The pain was increasing and the middle and ring fingers began to swell and have a red color and the nails became apparently dead. The medical attendant used codeine, to control the pain and applied a mild galvanic current, put the patient on proper tonics, and advised him to use hot applications.

---

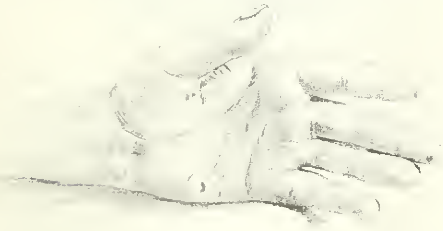
*Reported at semi annual meeting of Tioga County Medical Society

On May 28, 1902, his physician advised him to come to me, in hopes that static electricity would do him some good. It did not help him, it only seemed to increase the pain. By this time the finger nails were flattened and had slight ridges forming across them. Blebs filled with serum appeared on the ends of the fingers and at the base of the nails. The middle finger was bathed in a sticky perspiration and was becoming discolored. The pain was intense when the parts were exposed to the air. The patient was taking one-fourth of a grain of morphine every hour and was not relieved.



Having never seen a case like it, I consulted with Dr. C. H. Ott of the Robert Packer Hospital at Sayre, Pa., and we decided that it was a case of Raynaud's disease. I began giving $\frac{1}{100}$ grain doses of nitroglycerin three times a day, and tried mild descending current from a galvanic battery and mild massage of the parts. The pulse was not strong enough to be felt in the left arm from wrist to axilla. The nitroglycerin did not seem to affect the patient in any way; although the dose was increased to $\frac{1}{100}$ grain every three hours. The galvanic current, although very mild, caused the most excruciating pain. The massage gave very little relief. The middle and ring fingers had become a dark bluish-green color, the blebs on the ends were open and ulcerating, and the hand slightly mottled in appearance There was a marked fetid odor to the discharge from the fingers.

The patient lost his appetite and rapidly became thin. Could get no rest at all and threatened suicide.



At this date, June 23, he was getting twenty-four grains of morphine subcutaneously every day with no relief. Hoping to relieve the pain for a time at least, and maybe give him a possible chance of recovery by removing the offending member, I decided to amputate the arm. This was done in the Robert Packer Hospital at Sayre, Pa., on June 25, at 10 A.M., taking the arm off at the junction of the middle and upper thirds of the humerus. Patient was put to bed, and came out from under the anæsthetic in good shape, but was delirious. At 4 P.M. on the day of the operation the temperature was 101°F, pulse in the neighborhood of 130, respiration 28. I was giving one-fourth gr. of morphine hypodermically at 2 P.M. and 4 P.M. He apparently had very little pain. On the 26th he refused food or drink, spitting the water into the nurse's face. He remained in a state of delirium, grew weaker, and died on the 27th day of June at noon.

The illustrations show the general condition of the patient on June 20 and also the local lesion.

A Method for the Sterilization and Preservation of Catgut.—M. Claudius says that the many methods in use for the preparation of catgut-suture material sufficiently indicate the unsatisfactoriness of all of them. He proposes a technique which has many advantages and produces a perfectly reliable catgut. The ordinary raw cat gut is wound on glass spools and, without further preparation, is immersed in an aqueous solution of iodine and iodide of potassium. The formula for this is as follows: One part of iodide of potassium is dissolved in a small amount of water and an equal amount of finely-powdered iodine is added. When this has gone into solution, enough water is added to make a 1 per cent. solution. The container is marked with the date, and at the end of eight days the material is ready for use At the time of operation the catgut is placed for a short time in a 3 per cent. carbolic-acid solution or some indifferent sterile fluid, which washes off the superfluous iodine solution. If any unused catgut remains on the spool it is returned to the jar of iodine solution for future use. The sojourn in the iodine solution transforms the catgut into a black, wiry thread, which is very easy to tie and is extremely strong, the latter quality being greatly enhanced by the preliminary treatment in carbolic solution. The most important point, however, is that the material is absolutely sterile, as the author proved by a very detailed series of culture experiments. In fact, it is mildly antiseptic, this property affording an additional safeguard, since it eliminates the chances of a possible infection during the transit from the spool to the wound or from the patient's skin. It has been kept in the iodine solution for five months without deterioration in any respect.—*Deutsche Zeitschrift fur Chirurgie.*

Obstetric Paralyses.—Erwin Stransky says that the true obstetric palsies resulting from the actual events of parturition are to be differentiated from the cerebral groups, which have but little connection with the mechanics of birth, and from the facial palsies which are not infrequently observed after uncomplicated labors. They are therefore to be considered the autopathic obstetric palsies, and nearly always concern the upper extremity, though severe spinal trauma may produce analogous conditions in the legs. They are not very rare occurrences, though their ratio to the cerebral lesions is difficult to determine, but, at any rate, they are less common than the facial paralyses. As a rule, they are upper palsies; the lower portion of the extremity being less often involved and the entire plexus least of all. Exceptionally single muscles may be affected. The predisposing causes are disproportion of the maternal pelvis and the fœtus, protracted labor, and the expenditure of much force, exhausting disease of the mother, rigidity of the soft parts, and similar circumstances which effect asphyxia of the child or local asphyxia of an extremity, as in prolapse of the arm. If the damaged nervous apparatus of the child is now injured at some exposed point through obstetric trauma, paralysis will follow. It is of peripheral radicular type, and probably depends on slight neuritic processes in the roots, which may go on to secondary degeneration. If left untreated, the prognosis is usually bad, though not absolutely so, suitable treatment, however, nearly always effects a cure or great improvement. —*Centralblatt fur die Grenzgebiete der Medizin und Chirurgie.*

NATURE'S WEAPONS AGAINST DISEASE.

THE individual in bad health is seriously handicapped in the struggle of life, as also, to a lesser extent, is one who is not thoroughly sound. The highly successful person must be equipped not only with a keen intellect, but with a good physique and vigorous constitution. These remarks apply with equal fitness to a nation as to an individual. If a nation be composed of strong and healthy human units, the chief component parts making for material success are then possessed. On the other hand, be the race, on the whole, feeble and puny, its downfall is assured with undeviating certainty.

Now that most of the foremost nations of the world are widely engaged in manufacturing, and to a large extent are dwellers in cities, there is need of unceasing vigilance on the part of municipal authorities to take care that life may be lived under the best conditions obtainable. That, in short, "Nature's weapons against disease" should have fair play in the fight.

Dr. A. C. Latham of Cambridge, Eng., a few weeks ago delivered before the anatomy class of that university an eloquent lecture on this subject, in the course of which he said that microorganisms, unless they were present in large numbers, or unless they were possessed of unusually virulent or poisonous properties, were harmless to those in a good condition of health; that is, to those, whose resistance had not been so reduced by bad sanitary conditions, by an insufficient supply of food, or by disease, that they readily fell a prey to these microorganisms. What was necessary, then, in order to stamp out diseases which owed their origin to microorganisms was to destroy the supply of seed and to increase man's natural resistance. But nature's weapons, light and air, did much to accomplish both these ends. A large proportion of the bacteria were killed by the direct rays of the sun. In laboratory experiments this effect was very striking, many species being destroyed in the presence of sunlight and air in so short a time as from one to two hours. Diffused daylight was also detrimental to pathogenic microorganisms, though its action was less energetic than was that of direct sunlight. Many pathogenic species such as the pneumococcus, the pyogenic cocci, the anthrax bacillus, the cholera spirillum, the typhoid, diphtheria, and tubercle bacilli, were known to succumb to this influence.

The lesson to be drawn from these facts—although an oft-told one—is strikingly obvious, and its repetition can do nothing but good. Nature's weapons are, after all, the most effective against disease; and the chief of them are fresh air, all the sunlight that can be obtained, and plenty of rest.

The future health of the people demands that everything possible shall be done to keep away disease, and to conserve the vitality of the race. In cities, wide streets and open spaces in abundance must be provided, while all due attention must be paid to keeping sanitation at a high standard. The houses must be large, well-ventilated, and provided with plentiful facilities for admitting light. The air must be kept as free from coal smoke, dust, and other impurities as conditions will allow. There are many other needs which go to make the sanitarian's dream of the city of the future, but if those mentioned above were conscientiously carried out, urban life would not have the degenerating moral and physical effect that it too often exerts at present.

VACCINATION AND SMALLPOX.

CONTRARY to the belief of the anti-vaccinationists, but quite in accordance with the prescience of the far-seeing, smallpox has once again thrust itself into unpleasant notoriety. During the past two years there has been a recrudescence of the disease in the United States on an exceptionally wide scale, while London has been suffering recently from a virulent and extensive epidemic. Perhaps it required but little of wisdom, or foresight, to predict that the time was near at hand when there would be wide-spread outbreaks of smallpox in this country and in Great Britain. Such prognostications were based upon sound premises. The ground had been prepared, and only the seed was needed to cause quick germination and a fruitful crop. The neglect of vaccination in the United States, and the abolition of compulsory vaccination in Great Britain, supplied the conditions necessary to the origin and spread of smallpox. In both countries the long freedom from extended epidemics had served to give the people an unwarranted confidence, and to lull them into a false security, and vaccination had come to be regarded as superfluous and unpleasant, even by some as dangerous to health.

There are, however, signs that, in Great Britain at least, the leaders of the medical profession, together with many of the foremost men in science, religion, literature, trade, and social and philanthropic work, have awakened to a true sense of the danger of the situation, and have resolved, by all means in their power, to endeavor to educate the people to an appreciation of the great value of vaccination. The recent epidemic in London, which cost the community about 1,500 lives, and caused serious suffering to some 7,500 other persons, in addition to the pecuniary loss occasioned by the scare, will doubtless render the task of these educators easier, and will help to drive the lesson home.

The British Vaccination Act of 1898 will expire at the end of 1903, when fresh legislation will become imperative. In order, then, to educate public opinion in favor of vaccination, and thus to influence legislation, an imperial vaccination league has been formed, whose chief objects will be the study of the laws regulating vaccination, and the improvement of the vaccination law itself, and its administration.

A league of this nature should offset to some extent the pernicious teachings of those misguided enthusiasts known as anti-vaccinationists, who, up to the present, have almost had the field to themselves, and who have received a degree of attention by no means warranted either by their numbers or by their brains. The league a short time ago issued its first manifesto, which is distinguished by moderation and fairness, and absolutely bristles with pertinent facts. No desire is evinced to force its own views upon those who hold contrary but mistaken opinions, nor in any way to hold up to derision the ignorant and obstinate individuals who elect to evade or fight the laws, thereby endangering the lives of their fellow men. The aim of the league will be merely to state truths, and to leave the drawing of deductions to the intelligence of the public. Also, the best procurable expert opinion will be obtained, to suggest improvements in legislation and in the administration of the vaccination law.

The formation of such a league in Great Britain augurs well for the future of vaccination in that country, and should act as an effective counterblast to the one-sided arguments of its opponents.

Before leaving the subject, it may be said that the mildness of the type of smallpox in the United States at the present time has intensified the difficulty of dealing with the disease properly. Precautions necessary to stamp it out and restrict its scope have been neglected. Consequently smallpox has spread, almost unhindered, through the length and breadth of the land. The hope that it will continue mild may prove illusive, and, in any case, until strictly-enforced measures have been taken to stay the course of the malady, its dissemination will doubtless continue. It would be wiser, therefore, to treat this lingering epidemic as if it were of a virulent type, and to use every effort to extirpate it.

The example, too, of the leaders of science and thought in Great Britain, in endeavoring to impress the public with a just conception of the value of vaccination, might be, perhaps, followed in this country with advantageous results.

VENOMOUS SNAKES.

Dr. H. W. Crouse, Victoria, Tex., writes in the *Texas Medical News* on the venomous snakes and spiders of that State. It appears that Texas contains the greatest variety of venomous serpents of any State of the Union, while, as to spiders, the two species found to be venomous, the Latrodectus mactarus and the Phidippus tripunctatus, together with the entire group of spider-like species, the Tarantula, are within its borders,

Dr. Crouse gives an elaborate description of the poisonous snakes of North America, which it would here be superfluous more than briefly to notice. The differentiation of the three great types of snakes is in the teeth. All serpents have backward curved teeth in the upper and lower jaws. The innocent have two rows of ungrooved teeth in the upper jaw, the outer occupying the maxillary, and the inner the palatine bone. The outer usually number twenty to twenty-five. Snakes of a second type have rows of teeth in the upper jaw, furnished at the base of the maxillary row with a grooved fang, used by it for destroying its food, has been classified by Steineger as the Opisthoglyphs, thus denominating a genus which, while furnished with a venom apparatus connected with its grooved fangs, has but slight medical import, on account of the deep situation of the same, and the labial arrangement of the mouth, making it difficult, if not impossible, for this order to use their fangs while biting man. The division appealing to us for consideration, is supplied with fangs, anteriorly situated, one or two functionating, and several rudimentary. The former occupy the wedge-shaped maxillary bone, the latter the internal pterygoid and palatine bones. Thus, through the medium of the teeth alone, we are able to classify the various divisions; to differentiate the ones of venomous import, and thereby recognize, when we have the suspected snake's head which has bitten a patient, and what form of remedial agents should be adopted.

The exact composition of the venom of poisonous snakes has not been decided to the satisfaction of all investigators as yet. Prince Lucien Bonaparte took up the study of the poison secretion of the European viper in 1843, and discovered that it was an albuminous substance, with proteid principles.

In 1882 Weir Mitchell, with Reichert, separated three proteid principles from the original substance, which they proved to be albuminous. They named these substances venom peptone, venom globulin, and venom albumose. Finally Martin and Smith say the three proteids are, "one an albumin and the other two albumoses, the albumin not virulent, but the two albumoses corresponding to Hetero and Proto albumoses of Kuhne, and are extremely poisonous.

Referring to the symptomatology of the poison derived from all snakes, Dr. Crouse remarks that it has many common points; equally so that of the bite of venomous insects, such as spiders. From both originate local and systemic symptoms, which vary with the specie. In all there is pain, variable local swelling, and irritation to the cardiac, respiratory, and cerebral centers, blood changes, antibacteriolitic influences, all of these varying with the type of serpent or spider. The diagnosis of a venomous snake depends on several objective signs. The presence of one or two isolated punctures, variably separated according to size of snake, the local pain swelling and peculiar systemic symptoms, the history given by the patient, the type of snake, if the head has been secured, and the absence of two rows of teeth in the upper jaw, the presence of one or more functionating fangs, found by taking a pencil, pen, or small stick and stroking the mucous surface of upper maxillary; the presence or absence of a pit, thus separating the Cobra from the Pit Viper. The prognosis of the case depends upon many factors: The size of the snake, the type of the snake, the climate, temperature, size, and condition of patient bitten, point bitten, treatment used, etc.

The treatment of snake poisoning is varied. The old mechanical remedy, the ligature, says Dr. Crouse, applied above and below the fang punctures, accompanied by scarifying, cupping, or sucking of the wound, still justly retains first place in local treatment. The infection of one of the coagulating agents in the tooth wounds about the point of swelling, and followed by free massage, has been proved, when used early, to be capable of destroying the entire chain of dangerous symptoms following venomous serpent's bites.

Kaufman experimented upon four dogs, giving each, on the inner side of the thigh, two drops, hypodermically, of viper's venom. In one, five minutes afterward, he injected a bichloride solution, 1-1,000. In another, a potassi. Permanganate solution, 1 per cent. In another, a 1-100 chromic solution. On the fourth he used no antidote. The three dogs on which these antidotes were used recovered, the fourth dog died.

Calmette says he used successfully calcium hypochlorate solution, 1-60, specially prepared thirty minutes after inoculation of the animal with the venom.

Strychnine is the remedy which most effectually meets the systemic conditions present in venom poison.

Mueller of Australia says of this form of treatment: "While snake poison turns off the motor batteries, and reduces the volume and force of motor nerve currents, strychnine, when following it as an antidote, turns them on again, acting with the unerring certainty of a chemical test, if administered in sufficient quantities. Purely physiological in its action, it neutralizes the effects of the snake poison, and announces by unmistakable symptoms when it has accomplished its task, and would, if continued, become a poison itself. Previous to this announcement, its poisonous action is completely neutralized by the snake poison, and the latter would, therefore, be equally as efficacious in strychnine poison as strychnine is in that of the snake.

Japorandi or pilocarpine is recommended by some. Bancroft prescribes strophantus, while among other remedies used and advised are the following, given by the mouth: Calomel, iodide of potash, nitrate of potash, tobacco ashes, tincture of iodine and, hypodermically, caffein and atropine. Fayrer and Brunton advocate artificial respiration, while Calmette and Frazer claim to have produced immunity by the use of anti-venomous serum. Lavage is suggested as a remedy of much value in cases of snake poisoning.

Dr. Crouse, in concluding his article, summarizes the cardinal points indicated in treating a snake poison case as follows: (1) Local ligature above and below the wound, injections of local coagulating agents, such as pot. permang., 1 per cent. solutions, chromic acid, 1-100, etc., scarifying the wound, followed by cupping or sucking, massaging the swollen area, loosening the ligature at times to prevent strangulation, systemic treatment, strychnia to effects, frequently repeated, and atropine as a respiratory stimulant; pilocarpine, hypodermically, until it has produced profuse sweating, alcohol in small doses, ammonia rarely, then only early and in small doses; fluid extract of cedron seed in 5 to 10 min. doses. Stomach lavage, iodine, pot. bromide, and calomel, chemical agents neutralizing venom in the stomach; artificial respiration for hours; diuretics; diaphoretics, and purgatives. Finally, do not allow patient to sleep long at a time during the first twenty-four hours; also encourage the invalid, as deep mental prostration accompanies the poisonous influences of snake virus.

OFFICIAL SUPERVISION OF THERAPEUTIC AGENTS.

With the increase in knowledge that has come with the progress of time, gradual but marked change has taken place in the treatment of disease, and at the present day less implicit confidence is reposed in the effects of mere drugs than has been the rule in the past, while those that are employed are given in more convenient and less nauseous form. In order that the clinician may obtain physiologic results from the remedies he prescribes, it is necessary for these to be of known and determined activity. In the present state of affairs this condition is not always fulfilled, and we fear that it happens occasionally, if not often, that disappointment results from the use of inert medicinal preparations. The harm thus done is negative in character, being the result of deficiency or substitution and not of excess, of omission rather than of commission. On the other hand, the presence of certain injurious substances constitutes a source of even greater danger. This may result from contamination, accidentally or otherwise, by agents of toxic power.

For these reasons it would be extremely desirable to have some form of official supervision of therapeutic products, with the object of having the purity of these tested and their activity passed upon. The need for this has become all the greater since the introduction for therapeutic and prophylactic purposes of the products of biologic activity, as here accidental contamination with bacteria of pathogenic activity or with powerful toxins is possible, as is shown by the recent lamentable experience of the city of St. Louis in connection with the development of a number of cases of tetanus following the use of antitoxin in the treatment of diphtheria. This need is further emphasized by the occurrence recently of a considerable number of cases of tetanus in the sequence of vaccination as a means of protection against smallpox. It is true that the larger number of the latter are due to accidental secondary infection, but in some instances the development of several cases after the use of the virus of one manufacturer, and the exceptional discovery of tetanus bacilli in such virus, at least establishes the possibility of danger from this source. The best of the houses engaged in the manufacture of pharmaceutical products, of prophylactic and curative serums, of glandular extracts, and of vaccines, secure for these purposes the services of men of the highest scientific ability, while they are equipped with the most modern apparatus and appliances, and they exercise the greatest care to prevent accidents of the kind referred to, but occasionally some unforeseen contingency arises and disaster follows, while such an event may be expected at any time from the employment of the products of less responsible manufacturers. The foregoing considerations would seem to render unnecessary extended discussion as to the desirability and the need for some official control in this important matter. This could best be exercised by some central authority under the auspices of the national government, inasmuch as municipal or State control would require such a multiplicity or complexity of organizations as would scarcely work to satisfactory advantage. In the line of these reflections a bill was introduced into the United States Senate at its last session "to regulate the sale of viruses, serums, toxins, and analogous products in the District of Columbia, to regulate interstate traffic in said articles, and for other purposes." The objects of this bill are most worthy, and their effectuation would be a step in the right direction. The practice of medicine, and particularly the treatment of disease, is becoming daily more scientific, but precision in application and reliability of result can never be attained until the physician has assurance from some authoritative source as to the quality and the activity of the therapeutic agents he uses.

Virchow and the Parasitic Theory of Disease.

At this time, when the whole scientific world is ringing with the praises of the mighty pathologist just dead, it is in a high degree fitting to chronicle, or, rather, to call to mind his views on parasitism and infection. Virchow accepted the principle that infectious diseases are of parasitic origin, but he was not an ardent supporter of the parasitic theory of disease, and was opposed to the opinions now held by many that all diseases are of parasitic origin.

When the great German scientist delivered the Huxley lecture at Charing Hospital Medical School on October 3, 1898, he thus defined his attitude with regard to parasitism and infection. The following are his own words: "With regard to the subject of parasitism, the progress of scientific observation was retarded for centuries by the prevalence of the assumption made by Paracelsus that disease in general was to be regarded as a parasite. Pushed to its logical conclusion, this view would imply that each independent living part of the organism would act as a parasite relatively to the others. The true conception of a parasite implies its harmfulness to its host. The larger animal parasites have been longest known, but it is not so many years since their life history has been completely ascertained, and the nature of their cysts explained, while an alternation of generations has been discovered in those which are apparently sexless. Very much more recent is the detection of the parasitic protozoa, by which the occurrence of the tropical fevers may be explained. As yet we have not complete knowledge as to their life history, but we hold the end of the chain by which this knowledge can be attained. The élite of the infectious diseases are, however, the work of the minutest kind of parasitic plants, bacteria, the scientific study of which may be said to date from Pasteur's immortal researches upon putrefaction and fermentation. The observation of microbes under exact experimental conditions, and the chemical investigation of their products opened up the modern field of bacteriology, a science among the early triumphs of which were the discoveries of the bacilli of tubercle and Asiatic cholera by Robert Koch. In connection with this subject three important landmarks require comment. One is the necessity for distinguishing between the cause and the essential nature of infectious diseases, the latter of which is determined by the reaction of the tissue and organs to microbes. Secondly, there is the relation between the smaller parasites and the diseases determined by them. This may be summed up in the general word 'infection.' But to assume that all infections result from the action of bacteria is to go beyond the domain of present knowledge, and probably to retard further progress. The third point is the question as to the mode of action of infection. It is only the larger parasites whose main effect is the devouring of parts of their hosts; the smaller act mainly by the secretion of virulent poisons."

From a consideration of the foregoing, it will be observed that Virchow was of the opinion that it was premature to assume that all infections are of bacterial origin.

Eyesight Failing.

The Germans have been now known for a number of years as the bespectacled people of the world. The reason assigned—doubtless the right one—for the weakened sight of the Teuton is that it is mainly the close application to study for which he is distinguished above members of other races. Minute and painstaking research, involving almost continuous eye strain, has always been a distinctive characteristic of the student of the Fatherland, and it must be added that the results of this assiduous diligence, especially in scientific investigations, has been the gain of mankind.

For some time, however, the fact has been plainly evident that other nations besides the German nation are failing as to eyesight. Everywhere one goes one sees numerous individuals wearing glasses, and the habit is increasing at a rapid rate.

The New York *Sun*, September 28, publishes a dispatch from London bearing on this matter, which says: "Recent inquiries by oculists and opticians in England and on the Continent have developed the opinion that a few generations hence there will scarcely be a man or woman not wearing glasses. . . . This does not mean, apparently, that the eyes of each generation grow weaker. It is rather that the environment of modern civilization is inimical to healthy sight. Dust or fog play no small part in the troubles of the eyes, and traveling underground is also declared to be injurious. Then there is the hurried reading of small print, by which the reader lays up for himself impaired eyesight, with possible mental depression."

If it be true that dust is a prominent factor in causing defective vision, and that traveling underground is injurious to eyesight, then the outlook for the inhabitants of New York is the reverse of hopeful. Dust we have with us now, and in enormous quantities, and soon we shall have the underground. It may be expected, then, that in the course of a few years the man or woman who does not wear glasses in New York will be the exception rather than the rule. Perhaps, however, the hurtful influence of dust upon the eyesight has been exaggerated by the English writer, and as to traveling underground, so long as the tunnels are kept free from smoke and well ventilated, there should be no reason to apprehend that this manner of locomotion will be a menace to eyesight.

Failing eyesight is a deplorable but unavoidable concomitant feature of advanced civilization. It is one of the prices which we have to pay for living under modern conditions. Gas and the electric light have much to answer for in this respect. In order to retain eyesight unimpaired as long as possible, an individual should avoid poring over small print by artificial light, except when absolutely necessary.

Emergency Foods.

A problem, the solution of which has long been the aim of scientists and medical men in all parts of the world, is how to make a really sustaining food which can be packed into a small compass. Soldiers and explorers are more directly interested in the question than other members of the community, but, nevertheless, every one is more or less concerned in the matter.

At the time of the Spanish-American war the United States Army possessed no condensed ration which was satisfactory—in this respect being far behind the armies of Europe. Since that war, however, the War Department of this Government has bestirred itself, and now it is asserted that the army of this country has an emergency ration superior to that of any army.

Mr. H. E. Armstrong writes in *Ainslee's Magazine*, September, on the subject, detailing the result of tests made on three kinds of emergency rations by soldiers of the United States Army. A concentrated food to be capable of supporting life and sustaining strength for even a limited space of time must contain proteids, fat, and carbohydrates. The board appointed by the War Department to report on a ration decided that the emergency ration should contain at least 118 grams of proteids "and the largest amounts of fat and carbohydrates that can be combined to form a nourishing, easily digested food." Beef, beans, or peas offered the most proteids, but for the reason that in the first named these are most digested, beef was selected. More than 75 per cent. of parched wheat consists of carbohydrates. Chocolate contains 48.7 per cent. of fat, of carbohydrates 30.3 per cent., and of proteids 12.9 per cent., besides a small amount of salt. The latter two components were easily procured. To make the ration light and compact it was necessary to desiccate the beef, which in its fresh state contains 73.8 per cent. of water. Salt, which is essential to food, is found in all the components, except sugar. The dried beef—lean because it keeps better—and the wheat were ground fine and mixed together. Thus was produced a ration in small bulk, which will satisfy the healthy man and sustain his strength. Properly canned it will keep sweet in any clime.

Mr. Armstrong describes many other condensed foods used by the armies of different nations, as well as by explorers, sailors, sportsmen, and others who have need of such a form of diet, but the test to which the emergency ration chosen for the United States Army was put, would seem to show that it has no superior.

Charlatanism Past and Present.

Professor C. F. Martin, Honorary President of the McGill Medical Society of Undergraduates, took as the subject of his closing address "Charlatanism Past and Present." Much is heard nowadays of quackery, although this class are probably not so numerous as in the past

According to Professor Martin, charlatanism dates back as far as does history, and Hippocrates, 400 B.C., exclaimed loudly against quackery, against those who sought to cure epilepsy with amulets and charms, against those in whom superstition was uttermost in the treatment of disease.

"Paracelsus, again, was," says Dr. John Brown, "a renowned and ill-understood medley of evil and good, darkness and light, quackery and skill," but Paracelsus was in advance of his times, and really may be said to have laid the foundation of pathology.

It is curious that in this enlightened age the quack and advertising healer should flourish exceedingly and be able to gull so easily a large section of the public. Professor Martin thinks that this fact merely proves the sound sense of Pliny's assertion that any one with a sufficient stock of impudence may reasonably well pass for a physician. What applies to the early part of the eighteenth century applies with almost equal force to the early days of this our present twentieth century, and the lecturer supplied a striking instance of the truth of this statement. The following effusion was received from a man whose school of clairvoyance was such as to give him a handsome income, and will serve to illustrate the depth of credulity displayed by a large number of the community:

"Dr. —— ——, Clairvoyant and Botanic Physician. Terms of treatment, $5 per month, payable in advance. All medicines found.

"S—— ——, Maine, January 25, 1886.

"Mr. H——.

"Dear Sir: Yours received. The trouble in this case is caused by chronic disease of the liver and kidneys, which causes the blood to be sluggish in circulation, leaving the blood impoverished and impure, debilitating the mucous tissues of the kidneys, stomach and lungs, and debilitating the gastric juice of the stomach, also the nervous and muscular system. Consider the case can be helped. Notice head of letter for terms of treatment.

"Yours respectfully, "W. W. F."

There can be no doubt that at the present time commercialism is prevalent to a regrettable degree among the members of the medical profession, and Professor Martin thinks that charlatanism, in a small way, predominates with the regular physician who has had the advantages of a first-class university education.

There is undoubtedly a good deal of advertising in the daily journals in different parts of the world, and even this country has regular practitioners of medicine who think it no shame to thus attract attention to their ability and skill.

The plea, of course, may be entered that the competition is so acute within the medical profession that illegitimate means must be resorted to in order to gain a living. One remedy, however, is plain—that an elevation of the standards of medical education throughout the country would tend to relieve the strain to which the profession is put by reason of the unduly large number of medical men graduated each year.

Sanitary Problems of the Isthmian Canal.

Surgeon-General Sternberg writes in the *North American Review* of September upon this much discussed question, and gives some valuable advice as to the most efficient means to preserve the health of those engaged in its construction. The first and most important step to attain this object will be to ensure a pure water supply. This assuredly is of paramount importance, and should be carefully attended to before laborers are sent to any particular section of the line to begin work, and every possible sanitary measure calculated to keep away disease should be executed in advance.

Dr. Sternberg is, as is well known, a hard and fast believer in the theory that malaria and yellow fever are conveyed and spread by the agency of the mosquito. He, therefore, suggests that the men working upon the canal should be compelled to sleep under mosquito nets, a precautionary measure which should decidedly be enforced. The fact, of course, is well known that mosquitos, chiefly, attack human beings at night, who in a country swarming with the insects, as is both Panama and Nicaragua would be running neeless and foolish risks if not protected when asleep.

Dr. Sternberg also recommends that a sanitary service be established in connection with the Isthmian canal works similar in composition to the sanitary corps enlisted in the army.

News of the Week.

State Board of Medical Examiners of New Jersey.—At a meeting of the State Board of Medical Examiners of New Jersey, held at Newark, N. J., on October 1, twenty-three of the twenty-eight physicians who took the State examination held at Trenton N. J., on September 16 and 17, were duly licensed to practise medicine in New Jersey. The percentage of rejections for the September examination was eighteen. Beginning with the examination in June, 1903, each applicant will be required to file with his application a recent photograph of himself, with autograph signature, duly attested before and under the seal of a notary. In the matter of interstate reciprocity of medical license, the policy of the Board in endorsing the licenses issued by other States whose examining requirements are substantially the same as those of New Jersey, provided that the applicant fully meets the academic and medical requirements of the State, is gaining favor both with the profession and with other State boards. This policy places the admission of an applicant upon the basis of his personal fitness and the thoroughness of his examination which is believed to be the fairest and the most equable method of endorsement so far devised.

The Health of Havana.—According to the report of Dr. Charles Finlay, Health Officer of Havana, for August, the sanitary condition of that city continues good. No case of yellow fever originated in the city, but a man ill with the disease was brought by a steamer from Vera Cruz and died at Las Animas Hospital. Patients with yellow fever are not quarantined in the harbor, but are transported across land to the hospital. Concerning this, Dr. Finlay writes: "The success which has so far attended our efforts to prevent the propagation of the disease during the conveyance of patients from vessels in the harbor or from the immigration camp at Triscornia to Las Animas Hospital, as well as during their detention at that hospital, in this season of the year, is not only highly satisfactory to us as showing that our vigilance has not abated since the inauguration of the Cuban Republic, but also as an additional demonstration of the fact that in order to attain that result all that is needed is to guard the patient from being bitten by mosquitos." It is singularly appropriate that Dr. Finlay, the originator of the mosquito-theory of the propagation of yellow fever, should be the successor of Major Gorgas, who, acting upon this theory, drove the disease out of the city. The city death rate for the month of August was 22.81 per thousand, in which it compares very favorably with other cities of its size the world over, especially when the fact is taken into consideration that the city is without sewers. Dr. Finlay seems to have no fear that the Cuban Government will permit the sanitary condition of Havana to retrograde.

New Professors at Columbia.—With the opening of the new school year at the Medical Department of Columbia University (College of Physicians and Surgeons), Dr. Walter B. James takes the chair of the Practice of Medicine, and Dr. L. Emmett Holt that of the Diseases of Children. Dr. William J. Gies has been appointed Adjunct Professor of Physiological Chemistry in the University.

The Census of New York City Physicians.—According to the recently issued medical directory of the County Medical Association, there are 5,444 physicians in New York City, distributed as follows: Manhattan and the Bronx, 3,948; Brooklyn, 1,323; Queens, 115; Richmond, 58. In the State outside of New York City there are 5,162 physicians, giving a total of 10,606 for the entire State. The New Jersey list contains 1,655 names and the Connecticut list 1,103.

Ambulance Surgeons with Experience.—According to a new regulation which went into effect on October 1, the ambulances of Bellevue, Gouverneur, Harlem, and Fordham Hospitals will hereafter be in charge of the senior surgeons of the interne staff instead of the juniors, as heretofore. The new surgeons will have had six months experience in the hospital wards before having thrust upon them the very serious responsibility of dealing with all manner of accident cases. It is hoped that the private hospitals having ambulance services will follow the good example set by the city institutions.

The Beth Israel Hospital Alumni Association.—This society was organized in this city recently, its declared aims being "the promotion of social intercourse among its members, and the advancement of the science of medicine and the art of surgery." The officers are: *President*, Dr. A. Hymanson; *Treasurer*, Dr. George I. Miller; *Secretary*, Dr. M. Rabinovitz.

Chicago Surgeons Not Wanted.—The cable reports that Dr. Adolf Lorenz, Professor of Orthopedic Surgery at the University of Vienna, and Dr. Friedrich Mueller of the same city have started for Chicago for the purpose of performing a surgical operation upon a patient in that city. Are there no orthopedists in Chicago?

A Short Quarantine against Cuba.—Formerly the rule prevailed at this port of declaring a five days' quarantine against Cuba during six months of the year, from May to October inclusive, the five days counting from the date of sailing from Havana or other Cuban port. Owing to the absence of yellow fever, the quarantine period was shortened this summer by three months, the rule having been in force only from July 1 to October 1. It was not regarded as of necessity even for that time, but it was thought best to enforce the rule during midsummer, because of the possibility of unrecognized cases being carried to Havana from Mexican ports and then brought north.

A Visitation of Tarantulas in Seville.—According to the *Kleine Zeitung*, Seville and its neighborhood has been visited with a plague of tarantula spiders. Men, women, and children have been bitten, and are suffering cruelly. Although it has been scientifically proved that the bite of the tarantula is not really dangerous, and does not of itself inspire the bitten with the dancing mania, it is impossible to disabuse the ordinary Spaniards of their ancient superstition. As soon as the bite begins to work, the sufferer believes that he is compelled to dance, and that his dancing impulses can only be allayed by the tones of the "tarantela-guitarre." In Orsuna, as in other towns, there is a "Guild of Tarantula-players," says the writer, who earn considerable fees by sending round their members to heal the sufferers from the tarantula bite. The victim lies in bed, and as soon as his musical physician begins the monotonous clang of the "tarentela-guitarre" the patient rolls about wildly in the bed until he has worked himself into a fearful sweat, which carries the mild tarantula poison out of his body, and with the poison his mad desire to dance.—*The Hospital Gazette.*

Pathological Society of Philadelphia.—At a stated meeting, held September 25, Dr. J. Dutton Steele presented a specimen of chronic interstitial pancreatitis of syphilitic origin, in which, in contradistinction from the pancreatitis occurring in association with diabetes, the islands of Langerhans were preserved. Dr. David Riesman exhibited a specimen of aortic aneurysm, which ruptured into the right bronchus. The patient was a syphilitic, and he complained principally of pain in the chest, while physical evidences of aneurysm were wanting, except for the dilatation of the aorta shown in a skiagraph. In addition to the main aneurysm there were several other points of dilatation of the aorta. Attention was directed to the rarity with which aortic aneurysm ruptures into the right bronchus. Dr. M. H. Fussell exhibited a specimen of sarcoma of the pleura, obtained from a child that had presented symptoms of pneumothorax and, subsequently signs of pleural effusion. Tapping, however, failed to obtain fluid. On post-mortem examination the lung the right—was found greatly reduced in size and displaced, and the pleural cavity occupied by an enormous mass of neoplasm. Dr. Joseph Sailer exhibited a specimen of fracture of the skull with softening of the brain. The patient had been a man who was struck by a moving trolley car, and who developed symptoms that were thought to be due to delirium tremens. Death resulting, a fracture through the petrous portion of the temporal bone on the right side was found, together with subarachnoid hemorrhage on the convexity of the left hemisphere and an area of hemorrhagic softening in the temporosphenoidal lobe on the left side. Dr. Sailer exhibited also a specimen, aortic regurgitation, enlarged heart, and dilatation of the aorta. The patient during life had presented marked Cheyne-Stokes' breathing for a long time. The dilatation of the aorta was thought to be related to the increased amount of blood that had to be sent into this vessel with every contraction of the left ventricle, in order to compensate for the blood returned through the aortic orifice imperfectly closed by an incompetent valve.

Mr. Charles B. Ball, Professor of Surgery in Trinity Medical College, University of Dublin, recently delivered the Lane Lectures at the Cooper Medical College of California. On his return he was entertained in Chicago by Drs. John B. Murphy, William A. Evans, and J. Rawson Pennington, and in the evening, in the rooms of the Chicago Medical Society, he showed some beautiful colored slides of diseases of the rectum. Stereoscopic photographs were taken during his surgical operations in his Dublin clinic, by his son, and then subsequently rephotographed and colored with anilin dyes to bring out the salient features of each disease.

Obituary Notes.—Dr. John Byrne, for fifty-four years a medical practitioner in Brooklyn, died at Montreux, Switzerland, on October 1, aged seventy-seven years. Dr. Byrne was born in Ireland in October, 1825. He was graduated with high honors, from the Edinburgh Medical University in 1846 and in the following year had charge of a temporary fever hospital in Ireland during the famine. He came to America in 1848 and settled in Brooklyn. In 1853 he secured a medical degree from the New York University Medical College. He was one of the founders of the Long Island College Hospital, and organized St. Mary's Female Hospital in Dean street. He took the lead in the establishment of St. Mary's General Hospital, and from the date of its foundation was president of the faculty and chief surgeon of the institution. He was also consulting surgeon to St. John's Hospital, Long Island City. Dr. Byrne was a gynecologist of wide reputation, and an ex-president of the American Gynecological Association. A few weeks before his death he read a paper on uterine cancer before the International Obstetrical Congress in Rome. He retired from practice in February of this year, and went abroad, intending to devote several years to travel. A widow and two daughters survive him.

Dr. Thomas Wilde died at his home in Brooklyn, N. Y., on October 5, as the result of an accident which happened to him about a month ago. He was born at Port Huron, Ont., in 1837, and was graduated from the Bellevue Hospital Medical College in 1866

Obituary.

ABEL MIX PHELPS, M.D.,

NEW YORK.

Dr. A. M. Phelps, one of the most widely known and progressive orthopedic surgeons in this country, died on October 6, at the Post-Graduate Hospital following an operation two days before for cancer of the omentum. He was born at Alburgh Springs, Vt., January 27, 1851, and was educated in medicine at the University of Michigan, receiving his degree of M.D. from that institution in 1873. He had from the beginning of his studies a decided bent for surgery, and after graduation went abroad, studying for three years at the most renowned of the German surgical clinics. On returning to this country he became surgeon to the Central Vermont Railroad. He afterward settled at Chateaugay, Franklin Co., N. Y., where he practised from 1883 to 1887, and in this limited field, with its scanty material, he made for himself such a reputation as a bold and skilful operating orthopedist that he was called to this city to fill the chair of Orthopedic Surgery in both the University of the City of New York and the Post-Graduate Medical School. From 1885 to 1888 he also held the chair of Orthopedic Surgery at the University of Vermont, from which he was transferred to that of Surgery upon the retirement of the incumbent of the latter, Dr. J. Williston Wright.

Dr. Phelps was a member of the Medical Society of the County of New York, of the State Medical Society and of the American Orthopedic Association. In 1887 he was elected Vice-President of the Medical Society of the State of New York, in 1890 was chosen President of the same society, and in 1894 was President of the American Orthopedic Association. He was surgeon to the City Hospital, Visiting Orthopedic surgeon to the Post-Graduate Hospital, and surgeon-in-chief of the Daisy Fields Hospital for Crippled Children, at Englewood, N. J., of which he was one of the founders.

Dr. Phelps was known as an operating orthopedist, and was regarded as a leader in that school as disguished from those who rely chiefly upon mechanical measures in the treatment of deformities and chronic joint diseases. In the treatment of clubfoot especially he had little patience with those who endeavored to correct the deformity by subcutaneous tenotomies and the wearing of apparatus, and the open operation which bears his name was his protest against the methods of his more conservative brethren. He also devised a harelip operation, a wood corset for the treatment of spinal deformities, and several other orthopedic appliances. Dr. Phelps was a man of strong personality, who had firm convictions, which he never hesitated to express, and was known as a "fighter"; but his contentions were without bitterness, and arguments were expressed with fairness and left no rancor in the mind of his defeated antagonist. In his death American orthopedic surgery has lost one of its valued leaders, and many men in this city and throughout the country have to mourn the going away of an honest friend.

MORRIS JOSEPH ASCH, M.D.,

NEW YORK.

Dr. Morris J. Asch died at Irvington-on-Hudson, October 5, 1902. He was born in Philadelphia, July 4, 1833. He studied at the University of Pennsylvania, taking his A. B. degree from that institution in the class of 1852, and then entered Jefferson Medical College, from which he was graduated in 1855. Soon after graduation he was appointed clinical assistant to the elder Gross, occupying the position for several years. At the outbreak of the Civil War he entered the army, served on Sheridan's staff, and was the General's personal surgeon. He was officially mentioned for conspicuous gallantry on the firing line. He remained in the army after the close of the Civil War, and saw active service in the Indian wars. In the early seventies Dr. Asch resigned his commission, with the rank of major, to enter into private practice in New York City. His success was immediate, and he soon numbered among his patients many of New York's wealthiest and most influential families. He continued in active work until 1900, when ill health compelled retirement.

Dr. Asch devoted himself largely, though not exclusively, to the study and treatment of diseases of the nose and throat. In 1872 he was appointed surgeon to the New York Eye and Ear Infirmary, where he continued in active service till ill health forced him to resign, when he was appointed consulting surgeon. He became secretary of the Executive Committee of the Board of Directors in 1891, and was largely instrumental in shaping the policy of the institution and bringing it to its present state of efficiency. He was surgeon also to the Manhattan Eye and Ear Hospital from 1879 to 1902, and held a professorship of diseases of the nose and throat at the New York Polyclinic for some years. He was a member of the County Medical Society, the New York Academy of Medicine, the Roman Medical Society, the Medical and Surgical Society, and the American Laryngological Association. Though leading an unusually busy professional life, he found opportunity to keep fully abreast of the times, to contribute papers to various medical journals, and to collaborate in the preparation of several textbooks on diseases of the nose and throat. In 1890 he published an account of an operation he had devised for correction of deformity of the cartilaginous septum of the nose with a description of the instruments invented and a report of cases successfully operated upon. The operation is known as the Asch operation, and is extensively employed at the present time both in this country and in Europe.

As a man, Dr. Asch was modest, self-sacrificing, loyal and generous to a fault. His first thought, under all circumstances, was of others. Of a strongly sympathetic nature, and possessing to an unusual degree the power of inspiring confidence in his ability, his patients became his friends as well as his clients. His charities are known only to the many he befriended. His lasting reputation as a physician is established by the work he accomplished. His memory will ever be cherished by those who loved him.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ELECTION TO COUNCIL—SANITARY CONGRESS—SMOKE AND DUST PROBLEMS—TYPHOID IN WAR—SMALLPOX IN SHIPS AND PORTS—SANATORIA—BOOK ITEMS.

London, September 17.

This is the last day of the poll for the election to the general Medical Council, but counting the voting papers and the scrutiny will take four or five days, so that the result will not be declared this week.

We have taken the election quietly, though there has been some irritation among Sir Victor Horsley's admirers at a contest being forced upon him.

On the other hand, Mr. Smith's supporters say he is within his right, which cannot be disputed. Certain advanced reformers, as they deem themselves, were determined to test what they call principles. These I explained in my last letter.

Among the papers at the meeting of the Sanitary Institute was a rather original one by Dr. W. N. Shaw dealing with the problem of smoke in cities. It was certainly an appropriate subject for a meeting in Manchester, which has even a worse reputation than London for its smokiness. Dr. Shaw drew a parallel between smoke and sewage. He regarded one both as domestic or industrial refuse which had to be removed in some way or other. Peter Spence, many years ago, proposed municipal chimneys. Dr. Shaw suggests that each block of houses should be provided with the means of drawing off the smoke from all its fires into a chamber in which some treatment could be applied before discharging into the atmosphere. Architects of factories manage to carry the air of many flues into one channel. Why not apply the principle to all buildings? This being done, science would soon solve all the difficulties, and the question would become one of cost. Dr. Shaw estimated that it would require a tenpenny rate to get rid of smoke from the atmosphere of Manchester or London. Certainly that would give pause to ratepayers who have long been groaning under their burdens. But Dr. Shaw remarked that a year's fogs were estimated to cost from three to five millions sterling, and if that were so, a tenpenny rate would be cheap.

Sir J. Crichton-Browne, at a subsequent meeting, gave an address on an analogous subject—the dust problem. He said that the distance volcanic dust might travel had not yet been determined, but it was possible that that from the late West Indian eruptions might be reinforcing the black vomit of Manchester chimneys. Human agency increased the dust in the air. In the wilds of Argyleshire, tests had given 200 particles per cubic centimeter; in London, 150,000; in Paris, 210,000. Dust lowered the people's health, and when floating in fog increased the mortality. Industrial dust was responsible for an appalling amount of disablement and death. The potent remedy was ventilation, and humidity assisted. Wind and rain should have fair play and be supplemented by scavenging and by watering streets and pavements. Some domestic dust was inevitable, but the struggle against it must be kept up Wide streets and open spaces should be provided, back-to-back dwellings prohibited, and the height of all buildings restricted.

Simultaneously, presiding in the engineering section, Sir A. R. Binnie referred to the difficulty of removing all decaying matter, because sewage was generally waterborne, and such small quantities of decomposing matter rendered large volumes of water impure. Irrigation could not be carried out in our climate with the financial advantage once supposed. He feared some laxity was creeping in, due, perhaps, to improved purification of sewage. Large towns had expended millions to secure pure water, and London was running great risk in depending on the Thames and Lee, which receive more or less clarified sewage from a great population. As to a smoky atmosphere, when combined with mist or fog, it was one of the greatest evils of town populations. Electricity for lighting and gas for heating and cooking would be beneficial.

Perhaps the best discussion of all was that on Typhoid in War, elicited by a paper by Dr. Christopher Childs, who said the American commission on the Spanish war found that infected water was not the only factor in disseminating typhoid fever, but that personal contact and pollutions of soil were most important. He quoted Lord Wolseley's silly remarks, in the "Soldiers' Pocket Book," to the effect that he had never known the sanitary officer to make a useful suggestion, and recommending he should be left at the base. This explains the destruction of sanitary initiative and the despatch of an army to South Africa without any sanitary staff. I have often commented on Lord Wolseley's ignorant prejudice against the Medical Department. Lord Roberts holds a very different opinion and has publicly testified to the importance of a sanitary staff in all campaigns. What guarantees are there, asked Dr. Childs, that the War Office is fully conscious of the need of sanitary reforms or ready to carry them out?

Colonel Lane Notter, R.A.M.C., who acted as sanitary adviser during part of the war, said the country need not be ashamed of the state of things. He knew no hospital at home equal to the field and general hospitals constructed in South Africa.

Major H. H. Firth, R.A.M.C., representing the War Office, said the death rate from typhoid fever among the troops had not been 20 per 1,000, as was stated, but only 16 to 17. The authorities were quite alive to the importance of reducing it. But they must not expect the same results as in civil life. Those who said they did, "dwell in a fool's paradise."

Sir J. Crichton-Browne said there were no shortcomings in the medical department, which had done all that it could with the materials at its disposal. The withdrawal of so many men in the late campaign from typhoid fever prolonged the conflict, for had they not been removed it might have closed months earlier, and saved many lives, besides sixty or seventy millions of money.

Resolutions were passed recommending the study of the U. S. Military Camp commission and inquiring what measures the War Office is taking to institute a complete sanitary organization for the army.

Dr. Edward Walford, M. O. H. for Cardiff, brought up the subject of controlling smallpox on ships and in ports. The Notification Acts, he said, were of no use, as in the absence of a surgeon the master would omit to notify, or, if he intended to do so, his vessel was boarded by all sorts of people before he could, and a delay of hours might occur before the patient could be seen. Then there was no power to detain contacts or to require them to be revaccinated. He thought much of the incidence of the disease in the country was due to losing sight of these contacts. He advocated the transfer of the administration of the Vaccination Acts to the sanitary authorities.

There was a discussion on tuberculosis and sanatoria, in which some diverse views were freely stated, and the "Popular address" was delivered by Sir W. Collins, M.D., who discoursed on "Man *vs.* the Microbe."

Sir A. Conan Doyle has given £1,000, the balance of profits on his work on the South-African War, to the Edinburgh University to found a bursary in the Faculty of Medicine open exclusively to students from South Africa.

A book on consumption will be issued within the next few days by Dr. A. Latham, who, as I told you, obtained the first King's Prize. Vmraes's "War against Consumption" has already reached a second edition. It is printed on better paper, and the type is also improved.

Rose and Carless's Surgery has reached its fifth edition. A fifth edition has also been reached by Starling's "Physiology." There are other indications of the kind that the publishing season has begun and promises to be active.

THE MOSQUITO THEORY OF YELLOW FEVER INFECTION IN BRAZIL.

To the Editor of the Medical Record:

Sir: Until the present time the sanitary authorities of Rio de Janeiro have not made the war on the mosquito one of their methods of combating yellow fever, and it is only recently that the leading physicians here have accepted the "Havana doctrine," and even now some of the most eminent ones, while accepting the mosquito as *an* agent, do not believe it to be the *only* agent in the spread of yellow fever, and they rigorously defend the idea that the disease is propagated by fomites.

In Brazil the lawyers argue their cases, and fight their legal battles through the daily papers, and the doctors employ the same means to announce their discoveries and teach their doctrines. In yesterday's *Journal of Commerce*, the oldest and largest daily in Rio, Dr. Nuno de Audrade, for many years National Director of Hygiene, and one of Rio's most celebrated physicians, has a long article with the title, "The Prophylaxis of Yellow Fever," and as his views may be of interest to the readers of the Medical Record, I will send you a translation of some extracts from it.

He opens with the following just remark: "The discovery of the transmissibility of yellow fever by *Culex fasciatus*, or *Stegomyia fasciata*, introduces a new element into the prophylaxis of this pestilential disease, and helps to the comprehension of long-known and without explanation facts, which until now were inexplicable." As one of these formerly unexplained facts, he relates a personal experience of his in 1883. Contrary to the then generally accepted opinion that yellow fever was brought into the city from the shipping in the harbor, he acted upon the hypothesis that the shipping was infected from the lands, and to protect the vessels ordered them to anchor not less than 300 meters from the shore, and forbade them to touch the docks. At the time there were no cases either in the city or among the ships, but in the latter half of December cases began to appear in the city, and in the following months the disease became epidemic, but not until April of 1884 did the first case appear in the shipping, and this one was evidently carried from the land. By continuing this course in the following years, the epidemics of yellow fever were completely extinguished in a harbor where, in former years, they were so terrible that ships without number had their crews decimated. He then adds: "To-day more is known than in 1883. The Havana doctrine, confirmed by the studies of Reed, Carroll, Agramonte, and others, and inspired by the persevering observations of Finlay, revealed the agency of the *Stegomyia fasciata* in the transmission of yellow fever; and, as the natural history of mosquitos teaches us that they are poor travelers, it can be stated positively that the immunity of these vessels, separated from the shore, was due to the distance, which the mosquitos could not traverse."

Continuing, he says: "Another fact of great significance speaks equally in support of the Havana doctrine, and, perhaps, with greater brilliancy than the former. For fifteen years I have witnessed the immunity of thousands of non-immune persons, who, during formidable epidemics, have descended daily to Rio from Petropolis, returning at 4 or 5 P.M. Among these I do not know of a single person taking the fever, when the night was not passed here, but, on the other hand, I know many who took it when they impudently staid here over night. Now the *Stegomyia* hides itself during the day and begins to fly at dusk. This circumstance explains the well-known immunity of those who ascend to Petropolis. So, too, there are many cases in which yellow-fever patients have been carried to Petropolis, but I do not know a single one who became a *focus* for the spread of the disease. The altitude of Petropolis is not a serious obstacle to the propagation of yellow fever; but the *mosquito-vector*, which sucks the blood of the sick and injects it into the well, *does not exist there*." (Italics his.)

Petropolis is a mountain city, 2,700 feet above sea-level, about thirty miles north of Rio, and has about 25,000 inhabitants. It is reached by an hour's trip across the bay, and an equal time by rail, the last half of which is up an inclined plane. It is the summer home of the President and many Rio families, and the permanent home of all the foreign legations, and whenever their members have observed the precaution of not passing a night in Rio, they have always escaped; but this week the Chilian fleet has just left Rio with the remains of four ministers and secretaries of that country, who, during the last few years, did not observe this well-known law, and died from yellow fever. I am at present living in Petropolis, and I can, from personal observation, confirm Dr. Nuno's statement in regard to the immunity of those who go and come from Rio daily. One remarkable fact in this connection is that one taking the fever in Rio and going to Petropolis, even if the disease does not develop for a day or so, nearly always dies.

But to return to Dr. Nuno's article. He describes the experiments made in Havana, both those to prove the agency of the mosquito in the propagation of the disease and those to prove the inocuousness of families. Of the first he says: "These experiments are decisive and prove that the *stegomyia* inoculates yellow fever." He does not, however, accept as final the conclusions of the Americans in the second class, saying, "They conclude that such objects do not transmit the disease, and *deny the least value to their disinfection*. This statement, however, is not conclusive because the experiments were not well made. What can be inferred is, that the clothing, bedding, etc., do not transmit the disease *directly* [by direct contact translater], but do not prove that they do not *transport the germ*. To complete the experiment, there was lacking an indispensable element to the reasoning of prophylaxis; the presence of *healthy mosquitos*. These could infect themselves by these objects, and then inoculate men with the disease. The *lacuna* invalidated the inference." He sees the difficulty of his position, and, in a foot-note, says, "The foreseen objection that the anatomy of the feeding apparatus of the mosquito indicates that it nourishes itself by suction of liquids, but it does not destroy the value of our hypotheses; because it does not refute the possibility of the mosquito nourishing itself on any substance sufficiently moistened."

He cites several historical cases, which prove to his satisfaction that in many cases yellow fever has been developed where it was impossible to have had direct contact, by the mosquitos, which might have been the carriers, with the patients, who were the source of the infection, and, owing to the great difference in time, or in distance between them, there must have been external *media* of clothing, bedding, etc., to account for them. He says: "I confess that the hypothesis of the non-existence of the germ of yellow fever in external *media* has seriously disturbed me; because scientific documents, and my own observations, have piled up a world of facts, which are wholly unexplainable if the deductions of the American prophylaxis are accepted in their entirety." He concludes this argument as follows: "The Havana doctrine, then, in the part which excludes the yellow-fever germ from the external *media* is only a postulate—an interrogation; and does not authorize the exclusive prophylaxis which the Americans recommend; neither has it the force to impose the neglect, in the meanwhile, of the present methods of defensive hygiene. What it does positively prove is the ability of the mosquito to inoculate yellow fever. This discovery is equivalent to an illumination; but in a question of this kind it is well to accustom the eyes gradually to the light, so they will not be dazzled "

He also does not accept the conclusions of the "Americanos" that the "war against the mosquito" was the only, or even the most important, element in the stamping out of yellow fever in the Cuban city, but believes that the means of general sanitation of the city were important factors. In proof of this he refers to the fact that these measures were responsible for the reduction of the average annual death rate of 29.30 per 1,000 for thirty years to 22.11 for 1901, and quotes Dr. Gorgas as follows: "The American army took charge of the sanitary department of Havana in 1898, when the number of deaths reached 21,252 a year, and delivered it up with 5,720 deaths in 1901." From this he reasons that the methods which made such results possible were important factors in the fight against yellow fever. He also cites the results in New Orleans and in interior cities in Brazil, where the disease was stamped out long before the mosquito theory came into vogue.

He then comes to the practical application of the lesson to the needs of Rio de Janeiro, saying: "Yet be this as it may [the theoretical part], the consideration of the mosquito to-day forms an integral part in the prophylaxis of yellow fever. The 'war on the mosquito,' which the Americans initiated with the ardor of the Crusaders, ought to be waged with courage and without intermission. The administrative problem, then, is drawn in lines of living colors. Admitting that *Stegomyia* is the carrier, and (for the present) the only carrier, the necessity of its destruction follows without argument; it is the logical consequence of the established doctrine. To secure this result, the labor ought not to terrify, nor the expense to be considered useless. For fifty-two years yellow fever has strangled our progress, and it is already time for us to remember that we have a right to live. If the taxes which the people pay are not to be used to insure their life, I do not know for what they ought to be used."

He recognizes that the difficulties to be met in Rio are much greater than they were in Havana, Rio being two or three times larger, and, further, that here there is lacking the *power* to enforce the efforts of the authorities, such as the United States Army employed in Havana.

He outlines his future policy as follows: "Use all the present methods, and to them add those which have to do with the extermination of *Stegomyia*." He says: "*Addicão e não substitução* addition and not substitution."

Yellow fever usually dies out in Rio the latter part of May, or the first of June. This year, however, it has continued all through the winter, there being in June more cases than in any month before, and even now, at the end of August, there are a good many cases. This leads one to believe that now, as the warmer weather is coming on, with the start it has, it will develop into a severe epidemic during the coming summer, and it is to be hoped that Dr. Nuno's plan may be heartily supported.

H. S. Allyn, M.D.

Rio de Janeiro, August 27, 190

Urea in the Treatment of Tuberculosis.—At the British Congress on Tuberculosis, Mr. A. H. Buck described seven cases of external tuberculosis which were much benefited after the administration of urea, 30 grains three times a day.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 2, 1902

Contagious Conjunctivitis.—Myles Standish holds that in trachoma emptying of the follicles, followed by thorough antisepsis of the evacuated crypts, is the best treatment. The best method of accomplishing this result is by vigorously rubbing the surface with bichloride of mercury—1 to 500—conveyed on a cotton ball wound on the end of a stick. The results are surprisingly good, as in twenty-four hours the patient can open the eyes perceptibly wider, and the follicular stage, which formerly occupied from three to five months, has entirely disappeared. In gonorrhœal ophthalmia, he has found that protargol gives better results than silver nitrate. If the cornea have an infiltrated ulcer, however, protargol does not appear to have any extraordinary specific control of the corneal process. Many surgeons believe that these cases do better than they otherwise would, if the keratotomy of Siemisch is immediately done when the ulcers show any tendency to spread. In cases of diphtheritic conjunctivitis, treatment by antitoxin has given excellent results, the cornea not being involved after its administration.

A Case of Transplantation of the Biceps Femoris Tendon.—Charles F. Painter performed the following operation on a woman of twenty-eight years, who had been crippled to a considerable degree as the result of an infantile paralysis: The right astragalus was removed, and the cartilage covering the top of the scaphoid and the anterior extremity of the os calcis denuded, also that covering the external malleolus, and the tibia was moved as far forward as possible on this denuded area. Union took place by first intention, and two weeks later the biceps tendon was cut off at its attachment, and the muscle dissected free to such a height as would make it pull as an extensor when inserted into the quadriceps tendon, at the upper border of the patella. A slit was made through the expansion of the quadriceps tendon, close to the patella, and the biceps tendon was passed through this and fastened by two mattress silk sutures. The result is eminently satisfactory. The patient walks with the foot in a normal position, and the biceps is able to extend the leg to within 10° of complete extension, and to hold it there with the toes pointing upward; and is herself well pleased with the improvement.

Journal of the American Medical Association, October 4, 1902

The Classification of Chronic Nephritis.—J. B. Herrick offers the following scheme of classification, based essentially on that of Senator: (1) Chronic parenchymatous nephritis. (Chronic diffuse nephritis without induration.) (2) Chronic interstitial nephritis. (Chronic diffuse nephritis with induration.) *a*. Primary chronic insterstitial nephritis; *b*. Secondary chronic interstitial nephritis; *c* Arteriosclerotic kidney. (Arteriosclerotic interstitial nephritis.) (3) Mixed type, *i. e.* a combination of 1 and 2. The term "parenchymatous" can be used instead of "diffuse without induration" because, while not literally expressive of the true condition, which is more or less diffuse, it recognizes what is true—namely, that in this form the parenchymatous changes predominate; they are quantitatively greater than the second variety, in which the process, while diffuse, produces chiefly interstitial or stroma changes, with resulting induration.

Etiology of Chronic Nephritis.—A. R. Elliott starts with the premise that all nephritis is toxic in origin, and produced by the action on the kidneys of chemical or microbial toxins. Noxious substances are developed by altered tissue metabolism in the system, or are introduced from without. By their elimination through the kidneys they eventually produce organic changes in those organs. Hence, as causative factors in the production of the disease, we may have gout, chlorosis, diabetes, syphilis, the various cachexiæ, overwork, etc., and diseases involving certain excretory organs, such as chronic skin diseases, hepatic and intestinal affections. While it is comparatively easy to interpret the etiology of chronic nephritis secondary to some disease process which stands in direct relationship to it, there remains the large class of primary chronic nephritis, which does not offer the advantage of so easy an explanation, having no definite association with antecedent morbid perversions. This class of nephritis, comprising chiefly primary interstitial nephritis or granular atrophy of the kidney, is of extremely insidious development, and must depend upon the operation of some cause of very gradual and persistent character. Certain alterations in the vascular system, which are an almost constant feature of the syndrome of this disease, are no doubt, in the main, contemporary with the renal change, and produced by the action of the same irritant as causes the latter. In the opinion of the author, autotoxæmia of digestive origin is the great cause of primary contracting kidney.

Medical News, October 4, 1902.

Wandering Kidney, and the Results of Operation.—Clarence A. McWilliams gives the following resumé of the Presbyterian Hospital statistics of movable kidney. There were in all sixty-one cases; two occurred in men, fifty-nine, or 96.7 per cent., in women; thirty-eight, or 64.4 per cent., were married women; twenty-one, or 35.6 per cent., were single women. Of the married women, twenty-two, or 37.2 per cent. of the whole fifty-nine, had borne children. The average number of children to each was two. The right kidney was movable in fifty-three cases, or 86.8 per cent. The left kidney was movable in four cases, or 6.6 per cent. Both kidneys were movable in four cases, or 6.6 per cent. The average age was thirty-three and one-third years; the youngest was seventeen, the oldest, sixty-five years. Trauma was antecedent in only seven cases, or 11.4 per cent. As to complications, there was femoral hernia in two, gastro-intestinal indigestion in twenty-five, marked constipation in twenty eight, diarrhœa in three, jaundice in 1, chronic appendicitis in nine, urinary symptoms in eighteen, renal colic in seven, renal calculus in one, pyelitis in one, chronic nephritis in two, neurasthenia in eleven, general enteroptosis in three, uterine abnormalities in five. The results of operation were as follows: Forty-two cases followed after operation showed twenty-two, or 52.3 per cent. cured of subjective symptoms; fifteen, or 35.7 per cent., benefitted; five, or 10.9 per cent., no benefit. There were nineteen cases, or 31.1 per cent., of the whole number, uncomplicated. Of these twelve, or 63.1 per cent., were cured. There were twenty-three cases, or 34.4 per cent., which were complicated. Of these, ten, or 43.4 per cent., were cured. Recurrence occurred in six cases out of thirty-six examined or 16.6 per cent. The mortality of operation was 3.2 per cent., or two cases in sixty-one operations.

The Nervous Manifestations of Movable Kidney.—A. L. Benedict gives the results of the examination of 169 females: Of these, sixty-five presented movable kidneys, and two others depressed and palpable, but fixed right kidney. A number of others had right kidneys that could be oscillated a trifle, but scarcely enough to be considered movable, even in the first degree, or to produce symptoms. Thirty-five were nulliparæ, and thirty-two were multiparæ. Of the sixty-five cases, twenty-five had movability of the first degree only, but six of the twenty-five were affected on both sides. None of these presented nervous symptoms of any great severity, though often troublesome enough to the patient and her family. The remaining thirty-eight cases, excluding the two in which the kidney had become spontaneously fixed, or had been congenitally displaced, included one of insanity, one of suicide, two of contemplated suicide, at least two in which the family relations were seriously threatened by the nervous trouble, two of gastric ulcer, with its typic nervous state; one of hyperkinesis gastrica, one of general failure of secretory function, and other indications which led to the tentative diagnosis of Addison's disease; six not already counted, in which the diagnosis of nervous prostration, or some equivalent term, had been assigned, and without other adequate explanation. Of 200 males examined, seventeen had first degree right kidneys. Excepting a few of the men and a few women of the working class, all of the eighty-two cases emphasized their nervous condition. The writer adds that it is perhaps significant that so large a percentage as 8½ in men and 38.4 in women, should be met with in digestive practice. Taking the whole series of eighty-four, including the two of fixed kidney, the right kidney alone was involved in sixty-five, the left alone in four, and both in fifteen.

The Modern Treatment of the More Common Traumatic Injuries of the Eye.—Charles J. Kipp states that in all cases of suspected injury to the eyeball it is advisable to secure cleanliness of the skin of lids and the surrounding parts before proceeding to examine the eye. The free edges of the lids should be rubbed with bunches of absorbent cotton or sterile gauze, wet with a solution of 1 per cent. of carbonate of sodium, till all loose epidermis is removed, and this should be followed by a solution of bichloride of mercury, 1 in 1,000, applied in the same way. If the lashes are long, it is best to cut them short with scissors. If the skin of the lids is grimy, it should be cleansed with sulphuric ether, then with carbonate of sodium solution, and last, with alcohol. In all cases of injury to the cornea a very careful search should be made for disease of the lacrimal sac, as the secretion contained in the sac contains the pneumococcus in great quantity, which can cause extensive infection. In such cases care should be taken to cure, or, at least, to arrest at once the lacrimal disease. Local anæstetics are used very freely to enable a thorough examination of the eye and its appendages, and also for the relief of pain. In cases of blows on the eye from blunt instruments, cold applications to the lids will be useful in most cases and abstraction of blood from the temple will assist in subduing the inflammation. Cold applications are useful also in subconjunctival hemorrhage. Wounds of the ocular conjunctiva usually heal quickly, and require only that the secretion be frequently removed from the conjunctival sac. Sometimes a stitch or two will expedite matters. All wounds of the cornea, even though slight, if produced by unclean implements, require special attention. To remove foreign bodies, the lid is generally everted. If the foreign body is not found, search should be made for it in the cul-de-sac. A simple method is to pull the upper lid down by grasping the lashes, at the same time pushing the lower lid up, and then letting the upper lid go. The lashes of the lower lid will sweep it down. Foreign bodies *on* the cornea are easily wiped away by a cotton-tipped probe, wet with sterile water. If *in* the substance of the cornea, the body must be dug out with a sharp spud, or with a cataract needle. Perforating wounds of the cornea must always be regarded as dangerous. All large perforating wounds of the cornea and sclerotic, and especially those involving the ciliary body, are of an extremely grave nature, and their treatment should be left to the men experienced in such injuries. Rest in bed and cold applications are recommended until a specialist can be summoned. Burns of the conjunctiva and cornea are often very serious. The injuries caused by contact with strong acids, caustic alkalies, and escharotics, is very variable. Traumatic injuries to the eye are often the cause of litigation for damages, and it is of great importance that the physician should make a thorough examination of the injured eye, and also ascertain the exact condition of the uninjured eye.

New York Medical Journal, October 4, 1902.

A Case of Cheloid.—H. Taylor relates the case of a young man of twenty-one years, whose skin over the lower ribs, epigastrium, and hypogastrium was blistered by the application of a very hot poultice. Healing was followed in five or six weeks by the development of two lumps, which coalesced into a quite large mass, tender and painful. This was removed by operation, but recurred in three months, in the form of a double, hard, spindle-shaped mass, joined by a cross band, and was apparently inclined to invade adjoining tissue. There was none of the burning usually noted as a symptom. The author quotes the views of Virchow and Alibert as to the etiology of the lesion and mentions the points of differential diagnosis between it and merely hypertrophied scar. Nothing new is mentioned as regards treatment.

Beatson's Treatment of Inoperable Cases of Mammary Cancer.—J. G. Drennan believes that quiescence of ovulation has the effect of causing a greater supply of blood to the mammæ, thereby increasing lactation, if it is in progress, and that the removal of the ovaries causes a still greater vascular supply (spaying of cows); and that, in the case of lactation being altogether absent, there results from their removal a passive hyperæmia and a fibrosis of the glandular tissue, tending to obliterate the secreting tissue and to hem in the cancerous area, causing the germs to be killed by their own toxins. This fibrosis is, in all points, similar to that which occurs in any diseased glandular structure, liver, kidney, ovary, testis, etc. The fact of scirrhous cancer being the most frequent in this locality points to a fibrosis, the other forms occurring in the structures not so prone to fibroid changes. This curing of cancer or other germ diseases (and may not all disease be the result of them?) by hemming in the infected area may be produced in other ways, as by the administration, in large doses, of iron perchloride in erysipelas, thus causing a coagulated area around the diseased area, fatty degeneration changes not being a needful factor. After the germs have been destroyed by their own toxins the diseased tissue may be replaced by the action of healthy leucocytes and healing may take place.

A Method of Circumcision.—The method described by W. C. Klotz consists in the removal of a cuff shaped flap of skin, leaving intact the areolar tissue with its blood and lymph vessels. The patient having been prepared in the usual way, and the parts anæsthetized by infiltration with cocaine solution, the prepuce is retracted toward the root of the penis, and held moderately tense. A circular incision is made around the penis, from two to three inches behind the coronal sulcus, according to the amount of skin it is desirable to remove. This incision should divide only the skin as far as the areolar tissue. A second incision is made around the penis, about half an inch behind the coronal sulcus. This should be like the first, but in a plane placed more obliquely, so as to be parallel with the line of insertion of the glans. The two circular incisions are then joined by a longitudinal one along the dorsum of the penis, and, beginning along the edges of the latter, the cuff-shaped flap of skin outlined by the three incisions should now be dissected off all around the penis, either with a full-bellied knife, or with blunt-curved scissors. As a rule, there will be little bleeding. If the tissues are swollen from the infiltrated cocaine solution, strips of gauze, wrung out in hot salt solution, may be wrapped around the penis, and held with gentle pressure for a few minutes. The two edges are then brought together and united by interrupted horsehair sutures. Primary union takes place promptly, and the sutures may be removed about the fifth day. There is, as a rule, no swelling or œdema, and at the end of a week the skin is freely removable over the subjacent parts.

American Medicine, October 4, 1902.

The Pathological Relations of the White Blood-Corpuscles; a Case ot Hodgkin's Disease of Tuberculous Origin; a Case of Lymphatic Leukæmia. O. T. Osborne reports a case in which tuberculosis was undoubtedly at the bottom of the general appearance and manifestations of Hodgkin's disease. There was a decrease of nearly 1,200 leucocytes in seventeen months; the first count being 11,500. The second and more important case was one of lymphatic leukæmia. From a very careful study of this case, the writer concludes that (1) The lymphocytes are probably not the origin of the polynuclear leucocytes, else with so many lymphocytes—for at one count the white corpuscles numbered 380,000, and were practically entirely lymphocytes—we ought to have an increase of the more mature cells. (2) Normally, without medication to cause it, in lymphatic leukæmia, as has been observed by others as well as ourselves, the uric acid and phosphorus output is not increased, hence these cells do not break down more rapidly than in normal individuals with only 8,000 or more leucocytes. This means that a normal person with from 5,000 to 8,000 leucocytes has no more nuclear breakdown than these patients with nearly 400,000 leucocytes. (3) Arsenic, alkalies, and nusleic acid reduced the size of the glands and spleen in this case; but caused destruction of red corpuscles. (4) Nucleic acid alone seemed to reduce positively the number of the white cells. (5) The red cells and the general condition always and consistently improve under Armour's red bone-marrow. Hence it is justifiable to assume that in this case, if not in all cases of lymphatic leukæmia, the bone-marrow*is diseased. (6) The malarial infection reduced the number of the white cells and the size of the glands more than any treatment instituted.

An Analysis of Fifty-five Cases of Diphtheria.—Henry G. Godfrey considers in this report a series of fifty-five cases. The average age of the patients was 10.5 years. The sites of the lesions were the tonsil, the pharynx, the nasal mucosa, and the conjunctiva. There was no mortality. Prodromal symptoms were seen in twenty cases for a period of twenty-four hours or less preceding the development of definite lesions in the throat. Malaise, headache, pain on deglutition, and sore throat were usually complained of. An intense blanching of the face was highly characteristic. The temperature which had been elevated 1° or 2° during the prodromal period, took a sharp rise at the formation of the membrane, the acme being attained in twelve to twenty-four hours. There was no relation between the temperature and the severity of the infection. The pulse was accelerated out of proportion to the temperature in the prodromal stage, and increased coincident with the membrane formation. The membrane appeared first on one or both tonsils in thirty-five cases; as an exudate within the follicles of the tonsil in eight, in discrete patches on the wall of the pharynx in six; deeply hidden in a sulcus of the tonsil in four, and upon the nasal mucosa in two. Its extension was very rapid during the first twelve hours, after which intense œdema of the subjacent structures developed. Lymphadenitis was seen in twenty cases. It occurred early, and was usually unilateral. Vomiting was seen in twenty two cases—in ten at the onset. Concentrated diphtheria antitoxic serum was used in all cases in initial doses of 2,000 units or more. The injection was made in the subcutaneous tissues of the thigh. The average total dosage was 4,500 units. In one it was 20,000. Degenerations of the heart-muscle occur early in this disease. Antitoxin is not depressant to the heart. The persistence in the throat of the diphtheria bacilli is noteworthy—in one case for thirty-seven days. The average period was thirteen days. The complications in this series of cases were: Nasal hemorrhage, albuminuria (in two cases associated with casts). There were no palsies. Such untoward effects of the antitoxin as occurred appeared between the eighth and eleventh days, and were of short duration. The results in these cases seem to suggest that the larger doses of antitoxin consume the blood to a greater degree. The results of treatment by the serum alone have been unprecedented in the absence of mortality and in the infrequency and trifling nature of the complications.

Philadelphia Medical Journal, October 4, 1902.

A Modification of the Barker Method for the Treatment of Fractures of the Patella, with Illustrations.—H. T. Williams describes his method as follows: A double ligature is used, and in introducing the needle it can be directed either from above downward under the patella, if it is desired that the knot be tied below, or from below upward, if the knot is to be tied above. In introducing the ligature it is threaded double into the eye of the needle, after the needle has appeared at the opposite incision from which it is introduced. The two ends of the ligature are then held outside of the skin and the needle is withdrawn enough to bring it with the loop just beyond the opposite side of the fragments of the patella. Then, without withdrawing it from the wound, it is passed above the fragments and brought out through the incision at its first point of exit. The loop is then unthreaded from the eye of the needle and the needle withdrawn. In this manner the ligature is doubled around the fragments, and by not completely withdrawing the needle before it is passed above the patella it prevents the skin or subcutaneous tissue from being caught in the ligature as is apt to be the case in the Barker method. After the needle is withdrawn one end of the ligature is passed through the loop and, after pulling both ends tightly, they are tied firmly, thus making what is known as the Staffordshire knot. A little manipulation over the seat of fracture as the ligature is being drawn tight helps materially to arrange the fragments in their proper position. The ends of the ligature are cut off and the small incisions above and below the patella are closed with one or two catgut sutures, and the parts dressed antiseptically and the limb put in anterior and posterior splints. The advantages of this method are: The double ligature. The prevention of integument or subcutaneous tissue being caught between ligature and fragments; and by using the Staffordshire knot, the ligature can be more tightly drawn and the fragments held more closely together. The writer has applied this method in two cases with satisfactory results.

The Lancet, September 27, 1902.

Foreign Bodies in the Cornea.—W. Williams notes that when a minute foreign body, such as a little brown or black speck, is situated, as is generally the case, toward the middle of the outer aspect, the enlarged pupil, which follows the instillation of cocaine, makes it very difficult, and often impossible, to see the offending particle. To obviate this and to secure a clear view of the object to be removed, he finds it useful to instil a drop of eserine sulphate (1 per cent. solution), or preferably from 1 to 2 per cent. solution of pilocarpine hydrochloride, so as to neutralize the mydriatic effect of the cocaine. In this way one secures the anæsthetic effect of the cocaine without its drawbacks, for the eserine spreading the iris as a curtain behind the dark speck renders it visible and its removal comparatively easy, and that irrespectively of the direction in which the patient is looking.

Pythogenic Pneumonia. A. H. Copeman relates the history of a family, the members of which began to manifest, following the occupancy of new living quarters, bilious and feverish attacks. Then the eldest son was attacked with pneumonia. On the third day of his illness two other children came down with it, then the mother, and finally the father. The latter died on the sixth day of his attack, but all the others recovered. The chief features of the epidemic were (1) the very sudden onset; (2) the high temperature, and (3) the extraordinary manner in which the patients appeared to be prostrated from the very onset of the attacks. The sequence of events naturally directed attention to the sanitary condition of the premises. The official inspector reported that he applied the smoke test to the drains with the following result: In applying the test to the gulley in the covered yard, a direct communication was found to exist between the drain and the interior of the premises, the smoke finding its way from under the floors into the cupboard around the staircase. He also found an untrapped opening in covered yard (leading direct to drain) and a bell trap in the front area.

A Note on Syphilis in Relation to Life Assurance, with an Examination of 500 Consecutive Claims.—In the experience of F. P. Weber, as suggested by the title, syphilis played a part in the death of eighteen out of 500 persons, as follows: General paralysis, 8; tabes dorsalis, 4; brain disease, 3; cardiac and aortic disease, 3. At the examinations for insurance a history of syphilis was obtainable in only three out of the total of 500. Other interesting statistics from this series of risks are these: Most of the 500 were males, only forty-five being females. The males, aged sixty-five years or over, numbered 210 and the females twenty-one. The males who died before the age of sixty-five years numbered 236, and the females twenty-four. As stated above, in only three out of all the cases was a history of syphilis given, and in none of these cases did the syphilis seem to have anything to do with the death. All the three persons were males. One died at the age of fifty-six years from vesical calculus, ulceration, and hemorrhage; another died at the age of thirty-one years from tetanus, consequent on a fracture, and the third died at fifty-three years of age from shock connected with an operation for appendicitis. The last was a big stout man of the kind who bear operations badly; at the age of thirty-five years, when his life was accepted, he was six feet two inches high and weighed 252 pounds.

On Two Cases of Paralysis Complicating Gonorrhœa.—The cases occurred in the practice of T. R. Glynn. Case I was that of a man aged forty-eight years, who had gonorrhœa twenty years before, and again one month before coming under observation. Ten days before the latter, a feebleness was manifested in the feet and knees. This increased so that in three days he could scarcely walk. The later history of this case showed that the patient suffered from an ascending paralysis, and also from peripheral neuritis. The urethral discharge ceased at the onset of the paralysis, but reappeared on the cessation of the latter. The patient finally recovered after an illness of four months. Case II was that of a boy of seventeen years, who had suffered from gonorrhœa for two months. One month after the onset of the discharge he had pain in both knees and one elbow, without swelling. In a day or two his legs became weak, and symptoms developed pointing to a neuritis, involving the motor fibers of the peripheral nerves of the lower extremities, and causing muscular weakness and pseudo-tabes. He had also some of the stigmata of hysteria, such as general analgesia, some restriction of the usual field, tremors of the eyelids and hands, and some impairment of taste. A perfect recovery ensued. In this case also the discharge was absent during the active period of the nervous symptoms. The author adds that the probability of the correctness of the diagnosis rests upon the following facts: Peripheral neuritis is invariably due to some intoxication, often to bacterial infection. Many cases of peripheral neuritis have been set down to gonorrhœal infection, and experiment has indicated that the toxin of the gonococcus is capable of exerting a morbid influence on the nervous tissues—central and peripheral. In his patients there was evidence of gonorrhœal infection in the joint trouble, and no other source of intoxication could be discovered. He recognizes this to be a weak point in the argument, because in some few cases of multiple neuritis, poliomyelitis, and Landry's paralysis, no origin of intoxication can be recognized.

The British Medical Journal, September 27, 1902.

Cheloid in Vaccination Scars.—Henry Wiggins reports two cases, one a girl of eight years, the other a girl of fourteen years, whom he vaccinated in three places. The vaccination took well and followed the usual course. A few weeks later cheloid developed in each cicatrix. The lymph was the same that the writer had used for years. These were both primary vaccinations. The rest of the large number of cases that the writer vaccinated to the best of his recollection, were revaccinations. All of these gave most satisfactory results.

Rheumatic Myocarditis.—Theodore Fisher reports this interesting case. The patient was a girl, aged fifteen years. The right knee was swollen and painful, and there was some swelling of the metacarpophalangeal joints of both hands. A systolic murmur was present at the apex. "Harsh sounds" were heard at the base of the heart, which were possibly pericardial in origin. Still later rheumatic nodules appeared abundantly on the forearms and legs, and about the same time the pulse became rapid and remained about 136 to the minute. Then came a period of improvement but a vomiting attack occurred. This persisted, and, after three days, death took place. Examination of the heart showed fatty degeneration. The muscular pillars showed tabby-cat striation, and sections of the cardiac wall everywhere showed a patchy appearance, due to pale and opaque mottling. The mitral valve was slightly thickened, but the orifice was of normal size. The segments were fringed with small vegetations. Stained sections showed extensive degeneration. Not a fiber could be found that did not show granules and small globules of fat throughout its whole length. Cultures showed a rather small coccus, sometimes a diplococcus, but generally in short chains in broth, but like a staphylococcus on [illegible]

A Note on the Condition of the Central Nervous System in a Case of African Lethargy. W. B. Warrington reports the case of a Mandingo girl about seventeen years old. She had shown abnormal symptoms for about two months. The temperature was abnormal, the pulse about 70. She lay apparently asleep, and was roused with difficulty. She would then grunt or slowly answer questions which had to be repeated. Now and then she would indulge in long drawn out yawns. The skin was dry, scaly, and shrivelled. It evidently itched a great deal for, when roused, she continually scratched herself. Nothing abnormal was detected in the lungs, heart, spleen, or kidneys. The sternomastoid, axillary, and supraclavicular glands were felt but could not be seen. Systematic examination of the nervous system did not reveal anything abnormal. General sensation and the special senses were normal. The knee-jerks were present and equal, and the optic discs normal. Examination of the blood showed no filaria or malarial organisms. The patient seemed to improve under arsenic, and left the hospital for a time but returned in worse condition. The knee-jerks were now exaggerated, and there was a slight double ankle clonus, the pupils reacted normally and the optic discs were natural. After death the brain and spinal cord were saved, but not the peripheral nerves. The dura mater was normal, but the pia was considered to be thickened and slightly opaque, especially over the convexity of the brain and base of the pons. Stained sections showed it to be infiltrated with round cells. Parts of the cortex, the motor area, the frontal region, the basal ganglia, the pons, medulla, and cord, and the posterior ganglia were examined and all showed the same change—namely, the distension of the perivascular lymphatics with lymphocytes. The condition was evidently one of subacute leptomeningitis. In the cord a fair number of cells were found in the ventral cornua, which showed chromatolysis in various stages. No degenerated myelin was found in the brain; but in the cord, black granules were seen. According to Campbell, there seemed to be a slight general falling out of the nerve fibers, best seen in the radiary zone, where the inter-radiary plexus was deficient in density, the radiations of Meynert being unduly slender and the large oblique and transverse fibers lacking in number. In the radiary zone there was a curious patchy appearance, probably a manifestation of degeneration. No cocci were found resembling those described by the Portuguese observers.

Deutsche medicinische Wochenschrift, September 11, 1902.

Neurasthenic Neuralgia.—E. Jendrassik considers under this appellation a form of neuralgia which occurs in neurasthenic individuals and presents certain differences from the ordinary form of this disease. The pains are constant and not intermittent, as is the case in ordinary neuralgia. They are not strictly limited to a given location, but extend to regions which are in greater or less proximity to the involved site. Paræsthesias are generally present. The objective symptoms of ordinary neuralgia are not observed. Thus in neurasthenic facial neuralgias there is no local tenderness or redness or watering of the eyes. Motion of the affected parts gives relief, and the same frequently is brought about by pressure. At night the pains are usually less than during the day. The cause of the trouble is invariably ascribed by the patients to some local lesion. Thus in facial neuralgias the teeth are often regarded as the seat of the trouble. In all cases careful questioning shows that the patients are of the neurasthenic type, although this may not be at first apparent. The treatment presents the greatest difficulties. Operative measures are entirely contraindicated, as permanent relief is never obtained thereby. Internal medication is frequently unsatisfactory, although the various narcotics and anodynes give temporary relief. The best results are to be obtained by hygienic and general measures which are directed toward the rectification of the neurasthenic disposition. Nine cases of neurasthenic neuralgia of the fifth facial muscle are reported in detail.

Berliner Klinische Wochenschrift, September 15, 1902.

Intraglobular Methæmoglobinæmia.—S. Talma reports three cases. So far as the author knows, this condition has not hitherto been described. It consists in an intraglobular change of oxyhæmoglobin to methæmoglobin. The latter remains within the red blood cells and does not pass into the plasma. In all of the cases there was a cyanotic appearance and a dark pigmentation of the skin. When the blood was drawn it was dark in color and thick in consistency. Spectroscopic examination revealed the presence of the methæmoglobin in the red cells, but not in the serum. The subjective symptoms were principally headache, dizziness, and a general indisposition. The duration was from four months to over one year. All ended in recovery. The cause was attributed to intestinal autointoxication, since in all cases there was marked intestinal fermentation, and large quantities of indol and skatol in the urine

Munchener medicinische Wochenschrift, September 16, 1902.

Varicose Aneurysm of a Branch of the Saphena Magna which was Diagnosed as a Femoral Hernia.—Florian Hahn's patient was a woman thirty-nine years of age and had passed through a normal labor eight days previous to coming under observation. Upon standing a tumor appeared in the location of the external femoral ring which was painful, tender upon pressure and non-reducible. A diagnosis of femoral hernia was made, and as the pains increased and the tumor became dark in appearance an operation was at once underatken. Upon cutting down the true condition of things was ascertained. The varicose branch of the vein with its aneurysm was extirpated and recovery speedily followed.

Glycosuria and Tabes.—Ernst Meyer thinks that in certain instances in which diabetes and tabes are simultaneously present in the same patient the former is due to a tabic lesion located on the floor of the fourth ventricle, and is in reality analogous to the experimental glycosuria which is produced by a puncture in that region. To support this view a case is reported which gave the classical symptoms of both diabetes and tabes. A strict diabetic diet was without effect upon the glycosuria; neither did the abundant administration of glucose or other carbohydrates increase the amount of sugar in the urine. This latter fact shows that there was no inability on the part of the body to dispose of carbohydrates, but that the glycosuria was due to a lesion which could not be influenced by diatetic regulations. In the present knowledge it can only be supposed that such a lesion could be located in the nervous system, and in the presence of tabic alterations it is the most rational to ascribe it to such.

Treatment of Syphilis.—E. v. During believes in a combination of the symptomatic and specific treatment of syphilis. There is, of course, no doubt that mercury is a specific for this disease, but the indiscriminate and injudicious use of this drug produces in many cases a reduction of the general vitality of the patient and in all cases only gives the best results when used in moderate dosage and in combination with symptomatic and hygienic measures. The treatment of syphilis should never be commenced until the cutaneous lesions are manifest, both from the standpoint of correct diagnosis, and because of the moral effect upon the patient, whom it is necessary to impress with the seriousness of his condition in order that a sufficient continuance of the treatment may be obtained. The subcutaneous injection of mercury is to be preferred as a method of administration, as by such patients are kept under much better control than when the drug is given by inunction or by the stomach. For this purpose the salicylate is the best preparation. The injections should be given twice weekly, the dose being from .08 gm to 1 gm. This should be continued until all symptoms have disappeared. Indeed one or two injections should be given after this has occurred. As a rule from ten to fifteen injections suffice for this purpose. Turkish baths are of greatuse and should be takeneither the day before or immediately after the injections. Lesions of the mucus membranes should be treated locally with a 2 to 20 per cent. solution of chromic acid and the effects of the acid upon the tissues neutralized by washing with a saturated solution of the bicarbonate of soda. During the second month after the injections the patient begins to take the iodide of potash in daily doses of from .5 to 1 gm. This is continued for about a month. If there are then no symptoms present all specific treatment is discontinued. The patient is examined bi-weekly for another month and if symptoms develop the iodide is again ordered in the above dose. If no symptoms are present at the end of this time the iodide is given in about one-half the above dose for from one to two weeks. After this the patient is examined at from one to two monthly intervals and if necessary the iodide is given. The intervals of administration are thus gradually lengthened until during the second and third years only one or two treatments are given.

Subconjunctival Injections of Sodium Chloride in the Treatment of Retinal Hemorrhages.—Giacomo Rombolotti reports a case in which retinal hemorrhages were threatening vision For twelve days he injected a 2-per-cent. solution of sodium chloride in distilled water, and obtained great improvement in vision in the right eye. The left was more rebellious to treatment, but persistence in the injections produced an acuteness of vision of two-thirds. The ophthalmoscope showed that there were still some hemorrhages present, but the transparence of the retina was about normal.—*Gazette Medica Lombarda*, September 14, 1902.

Double Post-Grippal Ptosis.—Jacqueau describes a man, aged fifty-three years, having negative, personal, and family history. Two months ago he probably had the grip, for he suffered from anorexia, headache, and back ache. His indisposition lasted three weeks. He appeared to completely regain his health, when, four or five days afterward, he developed ptosis of the left eye, and on the next day, ptosis of the right. He presented a typical double ptosis. No disturbance of the musculature, either external or internal, could be found, nor any trouble with the fundus of the eye. Syphilis did not appear to be the cause of it. There was no trace of this contagion in the children of the patient. They had been born at term and were healthy. He presented no symptom of tabes. Jacqueau concludes that this is a case of post-grippal infectious paralysis.—*Lyon Médical*, September, 1902.

A Case of Traumatic Tetanus Cured by the Baccelli Method.—Giacomo Domenichini reports a case, which he intended to treat with Tizzoni's antitoxin, but was unable to procure any of it. He, therefore, resorted to the Baccelli method of phenic acid injections. These he gave every three hours, beginning with 1 c.c. and increasing to 2, and then to 3. On the first day he injected 16 c.g., in eight injections, each of 1 c.c. of a 2-per-cent. solution. The second day 24 c.g. were given in eight injections of 1½ c.c. each. From the third to the tenth day 32 c.g. were given daily in eight injections; from the eleventh to the sixteenth, a 3-per-cent. solution was used, and 40 c.g. were injected daily in eight injections of 2 c.c. each. Ninety-six c.g. were given finally from the nineteenth to the twenty-second day. From the second day of the treatment improvement was marked, and a complete recovery followed.—*Gazzetta Medica Lombarda*, September 21, 1902.

Syphilitic Arteritis of the Extremities.—Durandard states that, like all infectious diseases, syphilis can produce generalized lesions. The predominance of arterial lesions of syphilis is well known. Arteritis appears far more frequently in the tertiary period of the disease. Microscopically, there are two types of the lesion: obliterating and aneurysmal. The tendency to-day is to believe that the process starts in the external tunic. The arteries most frequently affected are those of the brain. Compared with these, the other arteries are far less frequently affected. Compared with other forms of arteritis of the extremities, syphilitic arteritis is relatively benign. When the lesions are not past hope, treatment is efficacious, especially when it is instituted in time. The best treatment is the administration of mercury with or without iodide of potassium. The hypnotics are useful in combating the painful symptoms. In the gangrenous types, when the process can not be influenced by treatment, amputation offers the only chance for the patient.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 25, 1902.

The False Anæmias.—Marcel Labbé declares that there is not a diagnosis that is made with more facility—even with thoughtlessness—than that of anæmia. When a patient presents himself with the functional and physical symptoms which are ordinarily attributed to anæmia, when he complains of lassitude, of palpitations, of vague digestive troubles, etc., if he be ever so slightly pale, the physician voluntarily labels his case "anæmia." If the patient is a young girl, if there are certain menstrual troubles, certain signs of neuropathy, it is named "chlorosis." This diagnosis ordinarily satisfies the patient, the parents of the patient, and the physician: the patient, because the word anæmia or chlorosis appears intelligible to her, and does not entail the fear of a dangerous affection; the parents, because this diagnosis confirms the opinion they had already formed, having judged from the pallor of the patient: the physician, because this diagnosis has not required of him long clinical researches, nor difficult intellectual efforts, and because he is going to order a treatment which is only too well known, and which will be gladly accepted by the patient. It is precisely this ease of diagnosis which is dangerous. Patients are often treated for anæmia who have only the one sign of pallor, of that disease. These patients may suffer from aortic insufficiency, from Bright's disease, from disease of the lymphatics, or of the thyroid. There is only one way of characterizing anæmia, of affirming its existence and determining its degree—that is, by examination of the blood. It is only after having made this examination, having counted the number of corpuscles, and having estimated the hæmoglobin, that one is justified in making the diagnosis of anæmia and instituting the treatment.—*Journal des Praticiens*, September 20, 1902.

Hydatid Cyst of the Lung Opening into the Bronchi.—Jacques Carles reports this interesting case. The patient was a woman of forty-six years, a resident of Bordeaux. She entered the hospital on account of intense dyspnœa and an incessant cough. She expectorated a clear liquid, a little reddish in color. This condition had suddenly developed after thoracentesis practised that morning. The personal history was negative. She had always lived in Bordeaux. Since childhood she had always had a cough. But there did not seem to be any pulmonary or bronchial lesion. The present affection had begun to trouble her some months before. It was thought at first by her physician to be pleurisy. An exploratory puncture was finally made, and a clear yellow liquid withdrawn. At the same time she expectorated a large quantity of fetid yellow pus, and suffered from an attack of suffocation. A second puncture was followed by the same results. She was then taken to the hospital. The expectoration changed to a red fluid, like wine. There was great dyspnœa. Auscultation revealed a large cavity in the median part of the left lung. Examination of the pus showed an enormous number of microorganisms of every kind, and some hooklets of the echinococcus. No hydatid membrane was expectorated, and the diagnosis was clinched by the presence of the hooklets. The patient was given frequent inhalations of aromatic substances, and pulmonary extract was administered. In case that the treatment should prove ineffectual, operation was advised.—*Journal de Médecine de Bordeaux*, September 14, 1902.

The Journal of Tropical Medicine, September 1, 1902.

Marking of the Tongue an Early Symptom of Ankylostomiasis.—A. B. Duprey holds that the peculiar marking of the tongue, described by one author as peculiar to ankylostomiasis, is in reality due to a staining of the mucous membrane from the chewing of a plant called phan. The condition recognized as ankylostomiasis is common in the West Indies, and is due to the inveterate habit of eating dirt or other filth, but the tongues do not present the condition described. The author mentions a very early sign of the disease, which may be detected before any palpable symptom of anæmia develops; namely, commencing atrophy of the skin consequent upon a condition of general innutrition.

Some Clinical Notes on a European Patient in Whose Blood a Trypanosoma Was Observed.—R. M. Forde reports a case in which the chief characteristics were: (1) An irregular intermittent temperature; (2) An œdematous condition of the face and lower extremities; (3) Rapid and variable pulse and respiration, unaccompanied by any evident cause; (4) Loss of weight with marked debility, wasting, and lassitude; (5) The persistence of these symptoms and their resistance to treatment. The only drug that produced any good result was arsenic (Fowler's solution), in graduated doses; there was a general marked improvement under its influence, but all the symptoms returned after it was discontinued for some time. Rest and light nutritious diet were the chief means of sustaining the patient's strength. The author presents a photograph of the parasite found in the blood.

Life History of the Ankylostoma Duodenale.—A. T. Ozzard found, by experimentation, that the embryos usually hatched from the ova in about twenty-four hours, when kept at ordinary temperature. During the rainy season, when the temperature is lower, they sometimes take a week before hatching out. In emerging from the egg, the embryo measures roughly from $\frac{1}{111}$ to $\frac{1}{100}$ inches in length, by $\frac{1}{500}$ inches in breadth. At this stage they show little else than an intestine and œsophageal bulb. They now increase rapidly in size and length, and undergo numerous ecdyses—perhaps two in the twenty-four hours. The embryos developed into free sexually-mature worms in from eight to ten days. The eggs in the free female worms are exactly similar in size and shape to those of the parasitic form. The size and shape of the free sexually-mature worms are, however, very different from those of the parasitic form, being very much smaller generally. The size of the free adult ankylostoma duodenale was, roughly, about $\frac{1}{27}$ inch in length by about $\frac{1}{250}$ inch in breadth.

The Edinburgh Medical Journal, September, 1902.

The Use and Abuse of Forceps in General Practice.—Michael Dewar, from the statistics collected, draws the lesson that there is much greater safety to both mother and child by a liberal, judicious, and careful use of the forceps, than when the labors are allowed to linger on, by the instruments being withheld for a long time, or not used at all, till the woman is quite exhausted, and her vital powers of resistance so lowered that she becomes extremely susceptible to the influence of disease germs, which are ever ready to take the upper hand. Of course the medical man should use the forceps merely to [illegible]

Some Neuroses in Childhood.—G. A. Sutherland writes of the nervous diathesis which is manifested in various ways, among others by local disturbances of function known as neuroses, and describes illustrative cases of functional tremors of the arm, spastic contraction of the right leg, functional aphonia and eructation, functional paraplegia, and functional difficulty in swallowing. Treatment should consist in removal from home, or isolation with a trained nurse. The child should be encouraged to use mind and body, and talking about ailments should be discouraged. All hygienic measures are to be employed and, above all, the child should be taught self-control.

Lobar Pneumonia in Young Children.—J. A. Coutts says that the principal points in the active treatment of croupous pneumonia in children are comprised in the efforts to control the temperature when excessive, to alleviate pain, to procure sleep, and to relieve the strain upon the right heart. Tepid sponging is efficacious in reducing temperature; the occasional use of a guarded dose of antipyrin is recommended. Alcohol can be given at the same time. Quinine can be prescribed with it. A single dose of opium, for the relief of pain when it is associated with hyperpyrexia and insomnia in the first "shock" of the complaint, is of great value. For the pain of pleural inflammation leeches or dry cupping are advisable. Insomnia may be due to constipation, in which case a copious warm enema will often induce sleep. As to cardiac failure, alcohol and strychnine are the drugs most to be relied on. As a last resource bleeding may be performed.

Atresia of the Conus Pulmonalis.—Edmund Cautley holds that we should be justified in dividing cases of congenital heart disease into two groups: (*a*) Cases due to developmental errors during the first two months of intrauterine life, the most probable cause of such defects being inherited syphilis. (*b*) Cases due to fetal endocarditis. Under the second group would be included all those cases of valvular lesions, leading to adhesion, contraction or destruction of valves, and many instances of delayed closure of the foramen ovale and ductus arteriosus. It must be borne in mind that the two factors may be coexistent in any one case, for endocarditis is more likely to attack a malformed than a sound heart. Moreover, structural defects, malformations, and endocarditis may be due to a common cause, which has begun to act in the embryonic stage of fetal life.

Russki Arkhiv Patologii, etc., July 31, 1902.

A Contribution to the Study of Cellular Poisons (Cytotoxins).—A Mankovsky, by injecting an emulsion of thyroid gland, mixed with a small amount of sodium chloride, into the abdominal cavity of cats, has found that after three injections the cat's serum was poisonous to the functions and cells of the thyroid body. Injected into the blood, the abdominal cavity, or the thyroid parenchyma of a dog, it caused symptoms similar to those which follow removal of the gland. A microscopic examination of sections of the thyroid showed a diminished amount of colloid substance, and a change in the lobules, with swelling of the cells, and cavities in the parenchyma.

The Cardiac Function in Old Age.—Charles Dehio says that old people are unable to accomplish hard physical work, not only because their muscles are enfeebled, but because the heart action is insufficient. The blood pressure curve is found to be very different in old age from that found in youth. The work which in young men causes 120 to 140 pulsations a minute, causes only 90 to 100 in old men. In youth, moreover, the curve rises at the beginning of work, remains high while the exertion continues, and falls to normal at its cessation. In old age the curve rises very gradually, and shows a tendency to fall during the continuance of exertion. It is evident that cardiac activity is, in large measure, lost in old age.

The Pathogenic Microbes in the Potable Waters of Kieff.—M. Moscaleff has made bacteriological researches into the potable waters of Kieff. No microbes were found in the waters from artesian wells. In that from ordinary wells, and from the river, the following microbes were found: (1) Staphylococcus pyogenes, aureus and albus, and citreus; bacilli pyocyaneus; bacilli coli; bacilli proteus vulgaris. (2) Non-pathogenous: Sarcina aurantiaca, lutea and alba; bacilli fluorescens liquefaciens; bacilli subtilis; bacilli mesent. vulgatus; bacilli megaterium; microc. ærogenes. The author also isolated a vibrio which was pathogenic for guinea-pigs and rabbits, and liquified gelatin in from twenty-four to forty-eight hours. The average number of microbes found in 1 c.c. of water from the Dnieper, was: In October, 2,223; March, 982; May, 2,444.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held September 22, 1902.

Frank Van Fleet, M.D., President.

Suppuration of the Middle Ear.—This was the general subject for the evening's discussion.

Etiology, Pathology, and Symptomatology of Acute Suppuration.—Dr. Edward B. Dench said that acute suppuration of the middle ear arose from the entrance of germs either through a solution of continuity of the drum membrane or through the Eustachian tube, but certain predisposing conditions must also exist. The middle ear was most commonly infected from the Eustachian tube. Acute suppuration was necessarily a common sequela of the acute infectious diseases which are associated with the presence of many pathogenic germs in the upper respiratory passages, as, for example, measles, diphtheria, and scarlet fever. The first symptom complained of was a stiffness about the ear, which was quickly followed by pain, rapidly increasing in severity. Ordinarily there was also an elevation of temperature, in adults to 99° or 101°F., and in children perhaps to 105° or even higher.

Complications of Acute Suppuration.—Dr. James B. Clemens discussed this subject. He said that the chief complication was diffuse otitis externa. Mastoid periostitis was frequently observed as a result of middle-ear suppuration. Inflammation of the mastoid cells was most apt to occur as a complication when there was delayed perforation of the drum and deficient drainage. Tenderness on pressure over the antrum and tip of the mastoid was commonly present in mastoiditis, and exceptionally pain was the only symptom. Cervical adenitis was often observed in acute suppurative otitis, but true suppuration of these glands rarely occurred. Retropharyngeal abscess might occur through an extension of pus through the Eustachian tube. There was a more or less localized meningitis, almost always associated with acute suppurative otitis media, in young children. A rapidly spreading inflammation was most commonly seen in those cases secondary to influenza.

Treatment of Acute Suppuration.—Dr. Wendell C. Phillips took up this topic. He insisted that rest in bed acted as a powerful abortive measure. The presence of adenoid tissue in the vault of the pharynx was a strong predisposing cause to acute suppuration of the middle ear. The exanthemata were responsible for many cases of suppuration, and much could be done in the way of prophylaxis by the systematic use of nasal irrigation. At the onset of the attack rest and free purgation with calomel were useful, and the pain could be relieved to some extent, and the inflammation checked, by irrigation of the ear, at intervals of half an hour, with sterile water at a temperature of 100° to 110°F. When there was evident bulging of the drum membrane, this membrane should be properly incised rather than punctured. After incision the canal should be kept clean by irrigation with weak bichloride solution, and bacteriological examinations should be made of the discharge, as a guide to both prognosis and treatment. Aside from the ice coil and the establishment of free drainage, there was very little to be done in the early stages. The ice coil should not be used for more than twenty-four or thirty-six hours, and the prolonged use of hot poultices should also be avoided, because of the danger of masking important symptoms. Persistent tenderness on pressure in the region of the antrum, together with bulging of the attack and posterior wall of the canal, indicated the need for operation. The exact time for the operation could not be measured by days or hours. It should not be forgotten also that early operation was usually followed by complete restoration of the hearing, a result not obtainable in many cases operated upon tardily. The general condition of the patient after operation demanded the use of tonics, such as freshly-prepared syrup of the iodide of iron. Uncomplicated cases of middle-ear suppuration under appropriate treatment always recovered in from two days to three weeks, and the responsibility for the untoward termination of such cases of suppuration must often be largely borne by the family physician.

Etiology, Pathology, and Symptoms of Chronic Suppuration.—Dr. M. D. Lederman was the author of this paper. He said that the pharyngeal space should be examined in all cases of chronic discharge from the ear, as the cause of the prolonged discharge would frequently be discovered by such examination. In children the infection entered the ear through the Eustachian tube very early, because this tube in them is wide and short. The position of the perforation in the drum often afforded a hint to the location of the disease. It was only in cases of long standing that the posterior wall of the middle ear became involved. Loss of hearing, with a persistent discharge, were the common symptoms of chronic suppuration of the middle ear. If the discharge were greenish and foul smelling, it would be safe to infer that there was necrosis of the bone. Pain was not a prominent symptom in these cases. In a person suffering from chronic otorrhea the occurrence of a chill with fever should lead one to at once suspect a fresh infection.

Complications of Chronic Suppuration.—Dr. Robert Lewis, Jr., discussed this topic. He said that among the more direct and obvious complications were a greater or less destruction of the membrana tympani, the formation of granulations and polypi in the adjacent cavity, the destruction of one or more of the ossicles, and necrosis of the tympanic wall. Above and beyond these, many infectious processes were at times set up in different parts of the body. With the exception of cases dependent upon tuberculosis or syphilis, all cases of chronic suppuration of the middle ear were the result of neglect of acute suppuration on this part. Of all the intracranial complications pachymeningitis was the most frequent. According to one writer, it was four times more frequent than sinus phlebitis, and twenty times more common than brain abscess. In 92 per cent. of the cases of brain abscess a fistulous tract connected the abscess with the ear, and in the large majority of instances the abscess was located in the cerebrum, usually in the temperosphenoidal lobe.

Treatment of Chronic Suppuration.—Dr. James F. McKernon, in taking up the treatment, defined chronic suppuration as that variety which had existed for six months or more with or without treatment. At the outset the nose and nasopharynx should be examined for abnormalities, and these, if present, corrected. Cleanliness of the auditory canal and adjacent parts should be at once secured. The location of the opening in the drum membrane should be ascertained, and whether or not drainage was sufficient. Usually the higher the perforation in the drum, the greater the involvement of the structures beyond. By cocainizing the part and exploring with the probe, the presence of dead bone could be determined. The "dry" method consisted in thoroughly drying out the canal with sterilized cotton, and introducing some antiseptic powder, and carrying a wick drain in deeply. This method of treatment seemed to be dangerous, except in expert hands, because of the liability to further infection. For this reason the modern practice among aurists favored the use of the "wet" method. The parts are irrigated with bichloride solution, one part to four or eight thousand of water, with boric-acid solution, twenty grains to the ounce, with a 1 or 2 per cent. solution of carbolic acid, or with a weak solution of formaldehyde or of permanganate of potash. The parts should be irrigated every two, three, or four hours, according to the amount of discharge using bichloride solution, one to five thousand. By means of the Valsalva method of inflation, the discharge could be dislodged from the less accessible portions, and then removed by irrigation. Of the astringent solutions used in the tympanic cavity, nitrate of silver, five grains to the ounce, was the most popular. There was a wide diversity of opinion regarding the use of hydrogen dioxide. It certainly reached all the parts very satisfactorily, but when the perforation in the drum membrane was small, he thought there was considerable danger of the evolved gas forcing the secretion back into the mastoid antrum, thus spreading the infection. In cases of long standing and extensive suppuration a radical operation was often necessary by which the mastoid antrum and the tympanic cavity were thrown into one. Systemic treatment should never be ignored in these cases.

Dr. Thomas R. Pooley, in opening the discussion, commented upon the rapid strides that had been made by otology in recent years. Mention had not been made by the the readers of the papers of the severe forms of acute inflammation of the ear not infrequently met with in the course of syphilis. It had been his experience in many cases of traumatic perforation of the middle ear that infection could be prevented by sealing up the opening by means of sterile cotton or gauze. He believed that the use of narcotics in any form should be completely eschewed in the treatment of inflammation of the ear. No doubt incision of the drum membrane was the proper thing in most cases, but, in his opinion, it was not necessary in all. In some cases the fluid in the cavity was only serous, and here simple puncture of the bulging quadrant of the membrane seemed to him adequate. One of the best ways of draining the middle ear in acute inflammations was by the insertion of strips of properly prepared aseptic gauze, the strips being introduced in such a way as to lie loosely in the depths of the auditory canal and projecting from the meatus. By capillary action the drainage could be made very effective in this way. He was sorry that Dr. Lederman had not dwelt upon the importance of repeated ophthalmoscopic examinations, to determine the existence of brain disease. Such examinations were important in both acute and chronic cases, but especially in the latter. Where there was choked disk present one could be sure of the existence of intracranial disease, and could be reasonably certain that there was sinuous thrombosis or chronic abscess of the brain. He had never been much in favor of the dry method of treating chronic suppuration of the ear, but he was heartily in favor of the local aseptic treatment of these cases by the "wet" method. Dr. McKernon had very properly given this local treatment great prominence, and this was especially fortunate, because, in the opinion of the speaker, the radical or Stacke operation had been too indiscriminately performed.

Dr D. B. St. John Roosa thought it would be well to disseminate the information that the Eustachian tube and the mastoid cells are essential parts of the ear, and not, as many seemed to think, rather remotely connected therewith. He desired to add still further emphasis to the great importance of rest in bed in the early stage of acute inflammation of the ear. He fully agreed with Dr. Pooley that it was not always necessary to make a large opening in the membrana tympani; moreover he considered that an unnecessary paracentesis of the drum membrane was a great deal more serious than the unnecessary opening of the mastoid process. The latter he did not consider an especially dangerous operation, but there was so much danger of infection from unnecessary and routine paracentesis of the drum membrane that he could not resist uttering a word of caution. In his opinion narcotics were of very little use in acute inflammation of the middle ear, and this was his chief objection to their administration in such cases.

Dr. Arthur B. Duel dwelt upon the improvement in hearing resulting from early and efficient treatment of these cases. Fortunately, the old notion that it was dangerous to stop a running ear had nearly lost its hold on the popular mind, and the modern aurist was allowed to treat other than inveterate and incurable cases referred to him by the general practitioner as a last resort.

Dr George B. McAuliffe alluded to the fact that the attacks of earache usually come on at night, and suggested that they were induced by the mechanical conditions present at that time. The influence of sound waves upon the inflamed ear was ordinarily ignored, yet in the treatment of an inflamed eye great care was taken, by the use of atropine, to prevent the disturbing influence of light. It was rather remarkable that the same physicians who would be horrified at the idea of incising any other part of the body and omitting to apply a surgical dressing were constantly performing paracentesis of the ear, and discharging the patient without even inserting into the canal of the ear a light packing of aseptic gauze.

Dr. Phillips said he only recommended the use of narcotics in adults and during the stage prior to suppuration. The spontaneous opening of the drum was usually a round aperture, which did not heal well; a free incision into the drum would promote healing. He had never met with a case of acute inflammation of the middle ear dependent upon influenza in which the fluid in the middle ear had not been distinctly purulent,

Dr. M. D. Lederman, in replying to the remarks of Dr. Pooley, said that while he would be very grateful for diagnostic aid from the ophthalmoscope or, indeed, any other source, he desired to call attention to the fact that in three recent cases of leptomeningitis complicating middle-ear suppuration the examination of the fundus of the eye was wholly negative.

Arthritis Deformans in a Child with Several Lymph Gland Enlargements and Splenic Tumor.—A. F. Lemke reports the case of a boy of eleven years with joint and glandular lesions, the diagnosis being for a time doubtful The axillary glands were enlarged so as to be visible from a distance, and the epitrochlear glands were the size of a hazel-nut. Tuberculosis was suspected, and one gland was removed and used for the inoculation of a guinea-pig, but the result was negative. During the period from the fourth to the eleventh year, he had cerebrospinal fever, pneumonia, and acute rheumatism. When he came under the observation of the reporter, the most conspicuous joint involvements were observed in the wrists and hands. The wrist-joints, particularly the carpal joints, were distended with fluid, but only slightly tender, and there was distinct joint crepitus. Crepitation could also be felt along the tendon sheaths as they passed over the wrist Some of these sheaths appeared to be distended with fluid The metacarpophalangeal joints and, to a more marked degree, the proximal interphalangeal joints were swollen owing to the accumulation of fluid and periarticular thickening. The elbows and shoulders were also involved, but to a lesser degree; motion in these joints was fairly well preserved. The knee-joints were much enlarged and also slightly distended with fluid. Crepitus was also to be felt over both knees. Complete extension of the legs upon the thighs was impossible rather on account of contractures of the flexor muscles than of the joint condition proper. There was some slight joint crepitus in both hips, and neither complete flexion nor extension of the thigh could be made by reason of the muscular contractures present. Both ankles were involved to about the same degree as the knees, the smaller joints of the foot showed comparatively very much less involvement than was observed in the hands None of these joints showed any evidence of acute inflammation, such as pain, redness, and an increase of local temperature.—*Chicago Medical Recorder.*

Clinical Department.

A MISPLACED APPENDIX.

By F. W. HEDGES, M.D.,
PLAINFIELD, N. J.

An appendix fourteen inches up the ileum, with no trace of an appendix attached anywhere to the cæcum. This, in brief, is the case I have to report. On June 4, of the present year, I operated on the patient, a young woman of twenty-nine years, for renal calculus, removing a stone one inch long and half an inch in diameter. It was the right kidney, and, in addition to a chronic pyelitis from the stone, it was a floater and made frequent and long excursions toward the pelvis. I anchored the kidney at the time of operation and the patient made an uneventful recovery, leaving the hospital one month afterward with the wound in the back healed kindly, save a small sinus, through which a moderate amount of urine still discharged.

During the next five weeks, living quietly at home, she was free from all the old pain in the kidney, but had two quite sharp attacks of pain with tenderness over the region of the appendix. The first attack lasted a couple of days, the second one a week, with typical symptoms of a mild catarrhal appendicitis, the temperature reaching 99.5° on several days. On putting one hand below the kidney and making sure that that organ was well out of the way, pressure with the other hand over McBurney's point would cause a good deal of pain. The removal of the appendix was advised, and on August 11 the abdomen was opened through the right rectus muscle. The small intestine presented, and while I was looking for the cæcum a loop of small bowel came out with a curious-looking appendix attached to it. It was at the point farthest from the mesentery, was an inch and a half long, half an inch wide at its base, tapering gradually to a blunt point. Of a structure seemingly identical with that of the small gut, not at all thickened, nor inflamed with no meso-appendix.

We remarked then that it looked like an appendix, but put it back and renewed the search for the cæcum. This was soon found and brought entirely outside the wound. There was no trace of an appendix attached to it anywhere. My brother, Dr. B. Van D. Hedges, who was assisting me, satisfied himself of the fact by a thorough examination, and four other physicians who were present were convinced that the young woman had no appendix anywhere about the cæcum, which was perfectly normal.

We then began to draw out the ileum to see if we could find again what we had at first mistaken for the appendix. We came to it fourteen inches above the cæcum, and a close examination showed it to be studded with tubercles, which had probably accounted for the pain in that region. Palpation over the course of the ureter revealed nothing, and the ovary was normal, while the kidney seemed firmly attached.

Recovery was uneventful, save for a sharp attack of ptomain poisoning on the tenth day.

POST-TYPHOIDAL PARALYSIS.

By P. L. BELLENGER, M.D.,
WATERPROOF, LA.,
EX-PRESIDENT OF THE PARISH BOARD OF HEALTH.

Cases of paralysis following typhoid fever, such as that reported by Dr. Isidore Ginzburg in the Medical Record of July 26, are not so rare as the reporter would appear to believe. While our country here is comparatively free from typhoid infection, in five cases, coming under my care within the last seven years, I have noticed this peculiar phenomenon twice. One, a woman patient, contracted typhoid fever on the 10th day of October, 1896. After running a typical course for five weeks, the disease terminated in total paralysis of both legs, which was fully recovered from in about six months without any special treatment, and the patient is now in perfect health, showing no evidence whatever of her former trouble. The second patient was also a woman, who contracted typhoid fever about the middle of October, 1896. After recovery she was partially paralyzed in one leg (the left). This was also recovered from in a few weeks without any special treatment. I mention these cases as being specially interesting, both coming in the same month and year and both in women of about the same age.

A NEW THEORY IN REGARD TO SEASICKNESS.

By E. CASTELLI, B.A., B.Sc., M.D., L.M., Dublin,
WASHINGTON, D. C.

I wish to call attention to a communication concerning seasickness, which was received from the Italian Ambassador to the United States, and which I consider worthy of consideration. The text of the communication is as follows:

"My Dear Dr. Castelli: Knowing that you are interested in the treatment of seasickness, I take pleasure in giving you my personal observations on the subject. After having found by experience that the only way not to suffer from seasickness was to lie in a horizontal position, I happened to notice that fixing my eyes upon a mirror while dressing (even when the sea was stormy) was sufficient to relieve the unpleasant sensations of seasickness. During my last ocean trip I tried this accidentally-discovered remedy, and always with good results. Take into consideration my observation and make it yours, if you think it may be of benefit to science.

"Mayor des Planches."

This clever observation may be another clue to the pathogenesis of seasickness. During my last trip, convinced of the possibility that cerebral anæmia was the principal cause of seasickness, I recommended to many travellers the use of red glasses in connection with the administration of euquinine for the purpose of producing hyperæmic condition of the brain, but the results were but slightly encouraging. My trip was from Geneva to New York, with a rather rough sea after leaving Gibraltar. What the distinguished author of the letter says, is, in my opinion, the demonstration that the pathogenesis of seasickness is the same as that of vertigo, *i. e.* the affection is the result of the *consciousness of the oscillation of the act of orientation.*

It is the same phenomena observed in a person who looks from the top of a tower on the surrounding country; the eye adjusts itself to all the different horizons that can be seen from the top—the tower being the center of the sky above and the earth below. The eye of the observer changes every few seconds to a different horizon, and has, in consequence, the sensation of the lack of equilibrium. We call that *vertigo*, which, in its highest form, manifests itself in pallor, cold perspiration, weak pulse, nausea, and vomiting—the same symptoms as those of seasickness.

Now, what happens on the ocean? At sea, the observer is obliged, in consequence of the rolling and pitching of the ship, to change the horizon repeatedly at brief intervals. He is, in other words, in the same condition as the person on the top of the tower.

I have not yet discovered if people suffering from vertigo are also affected by seasickness, or *vice versa*, or to what extent, but it would be interesting to have statistics on the subject, and to know if my idea would be confirmed.

What about the treatment? Why should the fact of looking in a mirror diminish the sensation of seasickness? Because eyes and mirror form one body and, the changing of horizons being reflected by a surface equal in every plane, the eye loses the consciousness of the different changes.

THE SUBCUTANEOUS USE OF PARAFFIN IN DEFORMED NOSES, WITH THE REPORT OF A CASE.*

By HAL FOSTER, M.D.,
KANSAS CITY, MO.

Dr. Roe of Rochester has done a great deal of original work in the correction of nasal deformities by surgical methods. Many others have followed him by devising several ways of correcting sunken-in noses, such as follow syphilitic perichondritis, leaving a saddle-back nose. The rhinologists meet patients with this deformity who are unwilling to submit to any surgical procedure. Corning of New York published his paper on the use of solidifying oils by injection into the tissues for mechanical purposes in the Medical Record, in December, 1891.

The writer read a report of a case treated by this method, by Dr. Heath of St. Paul, Minn. Dr. Gersuny of Paris was the first to use paraffin in saddle-back or sunken-in conditions of the nose. His articles were published in France, Germany, and America. His results were very good, and his patients greatly improved in facial appearance. Dr. Scanes Spicer of London recently reported a case in which he had successfully used paraffin in a saddle-back nose.

The paraffin should be sterilized, and every precaution taken to have the nose as clean as possible when the injections are made, in order that blood poisoning may not take place. The paraffin melts at 100° to 105° F. and solidifies at about the normal temperature of the body.

In the great number of cases now being reported, I have failed to find any case in which the paraffin was absorbed. Some writers caution against its use, saying that an oil embolism might result from its use. Meyer of Berlin has used the injection on animals, without any bad results. In some of his cases a very mild inflammation took place before encapsulation. He also used the drug to obliterate smallpox marks. Herman Smith of New York has reported several successful cases in which he had injected the paraffin.

Taking all this testimony from so many able men, I decided to try it myself. The patient was a boy, nineteen years old, from near Cowgill, Mo. He was suffering from constitutional syphilis, which was the cause of the nasal deformity, and was being treated for that disease by his family physician. The paraffin was sterilized, and a syringe, devised by Gersuny, was used. A few drops of 4 per cent. solution of cocaine was first injected into the part of the nose where the paraffin was to be inserted. I then, on January 20, 1902, under as thorough antiseptic conditions as I could, injected one teaspoonful of melted paraffin into the depression of the nose. It was rapidly moulded by the fingers and very soon became solidified, and the appearance was greatly improved. There was no pain during the operation. Ice may be applied to the nose for several hours after the operation to prevent inflammation.

I think there will be little danger of the paraffin doing any harm if rapid pressure is used immediately after the injection is made. Gersuny says several of his patients, some months after the injection, had typhoid fever, but the high temperature had no effect on the paraffin, it remaining in perfect apposition.

It is my opinion that this treatment, carefully used, will be of great assistance to rhinologists in correcting many of the unsightly, deformed noses which they meet.

---

*Read before the Missouri State Medical Association, at St. Joseph, Mo.

HYSTERICAL(?) HEMIPLEGIA

By L. W. GROSSMANN, M.D.,
NEW YORK.

Mrs. E., aged sixty, was in good health until present illness. On July 14 I was hurriedly summoned to see her. When I arrived at the house I found her propped up in a chair, supported by a number of women. On inspection I saw the following: the left eye was closed, the mouth was twisted to the right, the left arm and left leg hung limp. She was unable to speak coherently, muttering unintelligibly. She could not raise her left arm or left leg. I stuck a pin deeply into the affected side, at various points, without causing any pain. At this juncture a priest arrived, and together we carried the woman to bed. The reverend gentleman administered the last sacraments, and two minutes later the afflicted woman recovered. Her left eye opened, the mouth resumed its natural shape, she could raise her left arm and leg, and could feel the slightest pricking of a pin. An hour later she had a similar but much less severe attack. I prescribed a saturated solution of iodide of potassium, gtt x t. i. d., a mild laxative, ice-bag to the head, absolute rest in bed, and a fluid diet. Three days later I left her enjoying the best of health. Her previous history is negative. Her heart and lungs are normal. There is a moderate degree of arteriosclerosis, and a high-tension pulse. Was this a case of hysteria?

A VERY RARE FRACTURE OF THE LOWER END OF THE FEMUR.

By J. F. BALDWIN, M.D.,
COLUMBUS, OHIO.
SURGEON TO GRANT HOSPITAL, ETC.

F. S., a stout farmer boy, not quite eighteen years of age, was referred to me by Dr. L. G. Glenn of Kenton, Ohio. The patient had always enjoyed excellent health in every particular. On January 10, 1902, he was carrying a basket of corn, and in climbing over a low fence placed the basket on the top of the fence, and with his right leg upon the ground, threw the left leg over the top rail. At that instant, and while his entire weight was on the right leg, it suddenly gave way beneath him. He is not sure that his foot did not turn upon a cob or some other object upon the ground, but no investigation of this was made. He at once experienced severe pain in the knee and was unable to bear any weight upon it. He dragged himself to the house and was placed in bed. Great swelling of the joint came on, which did not subside for about two weeks. When this subsided sufficiently he was able to make out a movable body in the joint just to the left of the patella. This his physician regarded as probably a floating cartilage, and he was sent to me for operation.

At my examination on February 24 I found the knee somewhat stiff and tender, but with little, if any, swelling. The body seemed to be cartilaginous, could be distinctly outlined, and was entirely movable. I advised its removal, and this operation was made the next day. The body was exposed by an incision made at the inner border of the patella, seized with a tenaculum and removed, and the incision immediately closed and sealed. Care was taken to bring nothing but thoroughly sterilized instruments into contact with the wound. The body was found entirely detached, but, much to my surprise, instead of being an ordinary floating cartilage, it was found to be a portion of the articular surface of the femur, consisting of the cartilage and of the condensed bony layer immediately under it. Convalescence was immediate, and the patient left the hospital in one week with good use of the leg.

The only reference to a fracture of this kind which I have found in the literature at my disposal is that contained in volume I of Agnew's "Surgery." The author states that Volkmann of Halle described such an injury, and attributed it to the patient falling on the knee during flexion of the limb. Teale is also referred to as having had a case produced by direct impact of a cask slipping against the knee. Brodhurst is referred to as having met with cases. In Volkmann's case the removal of the detached piece was followed by complete recovery. In Teale's patient, erysipelas and death followed the removal.

If, as seems probable, such a detachment is the result of a direct injury, it seems quite strange that it should have occurred, as in my case, without any evidence of injury to the surface.

THE SUTURING OF ABDOMINAL OPERATIVE WOUNDS.

By G. K. DICKINSON, M.D.,
JERSEY CITY N. J.

The minor operation of closing an abdominal wound made for operative purposes has been the cause of much indecision and discussion, because of a want of proper knowledge of the functional anatomy of the parts, and sometimes because of a careless technique.

The opprobrium of intraabdominal work is incisional hernia. All methods of suturing have been followed by this untoward result; some more frequently than others. Methods most diverse, from the simple through thrust of the early operators to the elaborately-devised complex incisions of some of the later, have been exploited. It is as much a surgeon's duty to leave his patient with as strong an abdomen as before she came to him, as it is to do the operation successfully. The perfectly united incision never bulges and never needs a supporter.

That which tends to this result is first a primary union of each severed tissue to itself; next that the peritoneum shall be infolded that no adhesions of intestines or omentum may occur and that no depression on its surface may take the brunt of intra-abdominal pressure and allow of herniation. Another condition makes for failure: that is, pendulous abdomen with divergent and, perhaps, atrophic recti. It is doubtful if an abdomen of the latter type can ever receive a wound of sufficient size to permit of extensive work and be placed in as secure a condition as before. If time and conditions permit, the closure may be made as in the operation for umbilical hernia.

Following on the lines of the above suggestions, let the entrance into the abdomen be through the edge of one rectus with blunt dissection and perfect hæmostasis. Let there be as little bruising with hands and retractors as possible, and avoid spreading pus or other infected fluids on the wound. Close as follows: Pinch up a fold of the peritoneum a half-inch from the margin, and pass a needle, threaded with silk-worm gut, through its summit; a needle threaded to the other extremity of the gut is passed through the fold of the peritoneum on the opposite side. Take the needle on the left and pass it through the fascia and rectus of the right side; at the same time cross the right needle to the left, and similarly pass it through the left fascia and rectus. Cross needles again and pass to the skin and tie. This brings the peritoneum together, serosa to serosa, allowing of no depression, and brings the important divided tissues properly together, so that no empty spaces are formed to be filled with serum and blood, slow of absorption and easily infected.

The after care of the wound can be much simplified. Heavy swaddling gauzes irritate and itch, for which the patient pushes a hand under the dressing. They bring an excess of perspiration with skin bacilli to the surface, and, as evaporation is at a minimum, stitch holes may be infected. On the third day it is well to remove all dressings and binder, paint the incision with compound tincture of benzoin, and lay a single piece of sterile gauze on the wound, retained by adhesive straps. Often no binder need be used. A subcutaneous suture, neatly applied, makes a linear scar, but the lack of drainage often renders the attempt futile on account of unnoticed veins or small capillary ooze.

278 MONTGOMERY STREET

AMETROPIA; PUPILLARY CONTRACTION; WRINKLES.

By NORBURNE B. JENKINS, M.D.,
CHICAGO ILL.

Badly-shaped eye-balls cause small pupils, wrinkles, and facial distortion. The human face, severed from its bones, is funnel-shaped, with its muscles centering to its five openings. Darwin, Mosso, and Mantegazza have shown that the least irritation or impulse acts upon the face and its openings and produces expression or its distortion. Taking as a basis the extreme deformity of the face, and even of the body, that comes from chronic granulated eyelids, or trachoma, it is only natural to suppose that eye irritation is a common cause of facial distortion, perhaps the most common of all causes, of course excepting the shrivelings of age.

While a small pupil, squeezed-up eyelids, and looking through a pin-hole do not improve the distant vision of a perfectly-shaped eyeball, they noticeably aid a badly shaped one. When viewing distant objects the pupil of a perfectly shaped eye is normal in size, while that of an imperfectly shaped one is contracted.

In children the pupils are large and active, even in badly-shaped eyeballs, because the focusing lens is so soft that it makes images clear without the aid of the small pupil. As youth and age come on the lens hardens, when the small pupil and squeezed up eyelids are depended upon to make images clear, consequently the closing muscles of the pupil and eyelids over-develop, and the eyelids and pupil become squeezed-up and sluggish. Such strains and spasms may throw the whole face into wrinkles and frowns. Theoretically, glasses intended to prevent wrinkles should relieve all strain and entirely prevent any necessity for small pupils or squeezed-up eyelids.

Book Reviews.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Comprising Ten Volumes on the Years' Progress in Medicine and Surgery. Issued monthly under the General Editorial Charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol VIII Pediatrics and Orthopedic Surgery. Edited by W. S. CHRISTOPHER, M.D., JOHN RIDLON, A.M., M.D., and SAMUEL J. WALKER, A.B., M.D. Chicago: The Year Book Publishers, July, 1902.

IN his introduction the author states that although diseases of children constitute a very important part of pediatrics, the distinguishing feature of this branch of medicine—indeed, its key note—is the development of the child. He first considers, therefore, the growth and development of the child, and in this part he has inserted some very interesting tables and charts dealing with various factors, such as the average weight, height, vital capacity, etc., at different ages. He then proceeds to discuss nutrition, infections, mental activities, and anatomical and functional pathological resultants. The remainder of the text is devoted to the consideration of orthopedic surgery. This is a very attractive and valuable little reference handbook.

THE PRINCIPLES AND PRACTICE OF BANDAGING. By GWILYM G. DAVIS, M.D., Universities of Pennsylvania and Gottingen; Member of the Royal College of Surgeons, England; Assistant Professor of Applied Anatomy, University of Pennsylvania; Surgeon to the Episcopal, St. Joseph's, and Orthopædic Hospitals. Illustrated from Original Drawings by the Author. Philadelphia: P. Blakiston's Son & Co., 1902.

THE subject of bandaging is always of interest to both laity and physician. The writer points out the difference between the ancient and the present methods. The general kinds of bandages are taken up in order and described: The roller, the tailed bandages or slings, and the handkerchief bandages. The preparation and application of bandages are considered. The fundamental bandages are described, and the special bandages are classified according to the regions of the body to which they are applied. The book is intended for beginners, and the language is simple and direct, while technical terms are avoided. Although the present volume is based on a previous one by the same author, it is so changed as to be practically a new book. There are numerous cuts, which add much to the text and make the descriptions perfectly clear.

A BRIEF OF NECROPSY AND ITS MEDICO-LEGAL RELATION. Arranged by GUSTAV SCHMITT, M.D., Milwaukee. New York and London: Funk & Wagnalls Company, 1902.

THIS convenient little pocket edition is well fitted to the needs of the general medical practitioner, the lawyer, and the expert witness. The practical facts concerning the study, diagnosis, technique, and medicolegal aspect of a post-mortem examination are presented. The book is authoritative, and is a valuable contribution to practical medical literature.

A PHYSICIAN'S PRACTICAL GYNECOLOGY. By W. O. HENRY, M.D., Omaha, Neb. Professor of Gynecology in the Creighton Medical College. With five full-page Illustrations and sixty-one Illustrations in the Text. Lincoln, Neb.: The Review Press, 1902.

THIS little volume is intended as a guide book in gynecology for both medical students and physicians. Although it is concise, it covers a great deal of ground. The object of the author is to offer a practical guide in this subject to the general practitioner, so that he will be enabled to recognize and diagnose diseases quickly, and thus give the patient the benefit of early treatment. The equipment necessary for gynecological work is described; the varieties of gynecological diseases, the physical signs and diagnostic methods are discussed; and the genital organs, their anatomy and malformations are considered. The arrangement of the material is clear, and the appearance of the book is attractive.

TYPHOID FEVER. By J. T. MOORE, M.D., M.C.P.S., Professor of Theory and Practice of Medicine, Medical Department of Hamline University, Minneapolis, Minn. Chicago: G. P. Engelhard & Co., 1902.

THE monograph before us gives an excellent review of the subject of typhoid fever. It is primarily practical and meant for the general practitioner who has not at hand the larger libraries for consultation. The author has compiled from well-known authorities a concise description of the symptoms, sequels, and complications of enteric fever, and has done it well. The chapter on treatment, however, appears rather too short, especially since the excellence of the early portions leads one to look forward to as complete a conclusion. The author has incorporated his own ideas together with those of other writers, thus adding to the value of the work. The publication of these monographs, of which this is one of a series, promises to meet with great success, inasmuch as it furnishes fairly complete descriptions of separate diseases for those unable or unwilling to buy the larger systems. If they are all as good as the volume before us, the entire series will make a valuable addition to American medical literature.

DIE ANATOMIE UND PHYSIOLOGIE DER KEHLKOPFNERVEN MIT ERGANZENDEN PATHOLOGISCHEN BEITRAGE. Bearbeitet von Dr. A. Onodi, Professor der Rhino-Laryngologie an der Universitat in Budapest, etc. Pp. 179. Berlin: Verlag von Oscar Coblentz, 1902.

IN this monograph the author exploits his studies on the innervation of the larynx, covering a period of fifteen years. The manual is sharply divided into two parts; (1) The anatomical; and (2) the physiological. Onodi considers the various views promulgated, from time to time, regarding the relations of the vagus nerve to the larynx, and the question of the possible communication of nerve fibers coming from the spinal accessory for distribution through the vagus branches. Personally, the author does not adhere to the latter view. For him the vagus nerve is the nerve of the larynx. The distribution of the vagus branches is given in full, and their various physiological relations are discussed from all points of view. The monograph belongs to that class of publications we are accustomed to receive from Teutonic sources, a class that goes to the very bottom of things, though at times "the kernel of truth is wrapped in the husk of verbosity." Onodi has avoided this defect, and has produced a concise yet complete exposition of a subject of profound interest to laryngologists. It is one still under earnest discussion, and one on which the last word has by no means yet been said.

TRAITÉ DE MÉDECINE. Deuxième Édition. Publiée sous la direction de MM. BOUCHARD, Professeur à la Faculté de Médecine de Paris, Membre de l'Institut, et BRISSAUD, Professeur à la Faculté de Médecine de Paris, Médecin de l'Hôpital Saint-Antoine. Tome VIII, par MM. ANDRÉ PETIT et W. ŒTTINGER. Paris: Maison et Cie., 1902.

THE eighth volume of this second edition of the original Charcot-Bouchard-Brissaud treatise is devoted to the diseases of the circulatory system. The greater part of the volume is occupied naturally by Petit's study of cardiac disease, a most satisfactory presentation of the subject. The author does not advance any novel theories, nor advocate any especially new methods of treatment, but he tells the old story in a new way, and presents the entire subject in an intelligible and readable form. Shorter, but no less praiseworthy, is the article on diseases of the blood vessels by Œttinger. The author studies the lesions of the arteries and veins only, since the pathological alterations of the capillaries relate rather to local disease of organs, or to general systemic diseases. Of special interest in this article is the chapter on atheroma and arteriosclerosis. The volume, both on account of the intrinsic interest of the subjects treated, and because of the skill with which the writers have presented them, is one of the best of the series thus far published.

HANDBUCH DER PHYSIKALISCHEN THERAPIE. Von Dr. A. GOLDSCHEIDER UND Dr. PAUL JACOB. Teil II, Band II, mit 86 Abbildungen. Leipzig: Verlag von Georg Thieme, 1902.

THIS fourth volume completes the set, and the editors, as well as all their collaborators, should be congratulated upon the ending of so extensive and valuable a work. The present age in medicine is one of physical as contrasted with chemical or drug therapy, and every day almost one sees evidence of improvement in mechanical methods and apparatus. Electricity, light, massage, gymnastics, baths, and many other means toward cure are to-day administered in a more scientific and successful manner than ever before, and a work which discusses these measures from a truly scientific standpoint is a valued addition to literature. The lack of an index to complete this volume is to be regretted.

LES COURANTS DE HAUTE FRÉQUENCE EN DERMATOLOGIE. TRAITEMENT DES MALADIES CUTANÉES ET VÉNÉRIENNES. Par H. LEBON. Paris: Société d'Éditions Scientifiques et Littéraires, 1902.

IN an interesting brochure of sixty pages, the author discusses the production of light frequency and high tension currents, with diagrams and apparatus, and their application to skin, venereal, and inflammatory affections. Much of the clinical data concerns the experience of others.

Photographic Atlas of the Diseases of the Skin. By George Henry Fox, A.M., M.D., Clinical Professor of Diseases of the Skin, College of Physicians and Surgeons, N. Y.; Consulting Dermatologist to the Board of Health, New York City; Physician to the New York Skin and Cancer Hospital, etc. Philadelphia and London: J. B. Lippincott Company, 1901.

Parts X and XI of this atlas present a number of what a dermatologist would probably call "beautiful cases." Some of the pictures are very life-like, and while they might cause the layman to exclaim "how terrible!" the physician sees at a glance that the drawings and colorings are true to nature, though at times they might give an exaggerated idea of the gravity of the actual condition to one unfamiliar with the appearances of life and the true import of the lesions. The text is well written, in a brief or concise style, covering the essential points. The descriptions do not go deeply enough into the various subjects to make this a substitute for those textbooks which give the etiology and pathology at length.

For one located away from abundant clinical material, such a collection of colored photographs, made under the direction of one so well able to appreciate the requirements, is of the greatest value, and no doubt the sales of this new and improved atlas will outstrip those of former efforts in the same direction.

A Text-Book of Practical Therapeutics, with especial reference to the application of remedial measures to disease and their employment upon a rational basis. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics and Materia Medica in Jefferson Medical College of Philadelphia, Physician to the Jefferson College Hospital, ect. Ninth edition, enlarged, thoroughly revised, and largely rewritten. Philadelphia and New York: Lea Brothers & Co., 1902.

There is little to say of the present edition of Hare's well-known treatise that has not already been said repeatedly during the twelve years that have elapsed since the work was first offered to the profession in 1890. In this edition the text has been revised wherever change has been necessitated by the introduction of new remedies or methods, particularly in the chapter treating of medical measures other than drugs.

The book is divided into four parts. I. General Therapeutical Considerations, including the modes of administration of drugs and their classification. II. Drugs, in which each of the pharmacopœial and more important of the non-official remedies is treated of in alphabetical order. III. Remedial measures other than Drugs and Foods for the Sick. IV. Diseases, this being a guide to the practical application of the information contained in the previous sections of the work. A dose-table and two indexes, one of drugs and the other of diseases and remedies, complete the volume. Hare's Practical Therapeutics is evidently destined to lose none of its deserved popularity so long as it is subjected every year or two to such careful and satisfactory revision as the present.

How Can I Cure My Indigestion? By A. K. Bond, M.D., Member of the Maryland Public Health Association, Formerly Professor in the Baltimore Medical College, etc. New York: The Contemporary Publishing Co., 1902.

This little book is written in a popular way, and is intended to teach some of the essentials of hygiene to the dyspeptics. Good common-sense principles are recommended, but there is nothing new in the author's text which is not understood by medical men although, perhaps, not always put into practice.

The Schott Methods of the Treatment of Chronic Diseases of the Heart with an account of the Nauheim Baths, and of the Therapeutic Exercises. Illustrated. By W. Bezly Thorne, M.D., M.R.C.P. Fourth Edition. Philadelphia: P. Blakiston's Son & Co., 1902.

In the fourth edition of this excellent manual we find two entirely new chapters; namely, one on the physiological action of the baths and exercises and one on what has been termed the "after-cure." The book gives an account of the baths and waters in use at Nauheim, together with a full description of the resisted movements, which are explained diagrammatically as well as in the text. A number of illustrative cases are given, with graphic charts of the areas of cardiac dulness before and after the treatment, and also many sphygmographic tracings, which undeniably demonstrate the value of the methods employed. The work should stimulate the employment of these procedures in a field wider than heretofore.

The Theory and Practice of Infant Feeding. With Notes on Development by Henry Dwight Chapin, A.M., M.D., Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital; Attending Physician to the Post-Graduate, Willard Parker and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital. With numerous Illustrations. New York: William Wood & Co., 1902.

In this volume we have a most practical guide to the scientific feeding of infants. Not only are the details of the most approved methods given, but also the reasons therefore, which insures an intelligent management of different cases with their individual peculiarities. The author compares the milks of different animals, showing their adaptation to the special alimentary canals which are to receive them, and deduces from these facts the reasons for the difficulties of artificial feeding compared with that of nursing.

The subject of milk marketing is thoroughly considered together with the tests employed for determining the richness and purity of milk, the sources and dangers of contamination, and how to differentiate the various bacilli. The subject of infant development is specially new and interesting, and in it Dr. Chapin points out the importance of milk as an agent to that end. The illustrations are practical and the text remarkably clear, in no instances leaving the reader in doubt as to the ideas or methods of the author. The system of cross references has enabled the writer to concentrate his subject matter without loss of clearness, and it also helps the reader to obtain a connected idea of all topics under discussion. The book, as a whole, will prove interesting and instructive reading to all who have to do with milk, from the farmer to the physician.

Kurzes Lehrbuch der Krankheiten der Oberen Luftwege. Von Prof. Dr. Holger Mygind in Kopenhagen. Berlin: Verlag von Oscar Coblentz, 1901.

This manual is appropriately dedicated by the author to the memory of his illustrious fellow countryman and citizen, Wilhelm Meyer of "Adenoid" fame. The author was, in fact, one of Myer's pupils. The contents of the manual traverse familiar ground without presenting anything essentially new, though some of the illustrations of the shape and relations of the nasal structures are rather novel. The manual is well printed and contains all the essentials for students. It is hardly complete enough for the general practitioner, who seeks more than a conventional acquaintance with the problems of modern rhinology and laryngology.

The Canada Medical Act.—An act to provide for the establishment of a medical council in Canada was passed by the Canadian House of Commons in the early part of the present year.

It is set down that the purposes of the council shall be to promote and effect: (*a*) the establishment of a qualification in medicine, such that the holders thereof shall be acceptable and empowered to practise in all the provinces of Canada; (*b*) the establishment of a register for Canada of medical practitioners, and the publication and revision, from time to time, of such register; (*c*) The determination and fixing of the qualifications and conditions necessary for registration, including the courses of studies to be pursued by students, the examinations to be undergone and generally the requisites for registration; (*d*) The establishment and maintenance of examiners for examination and for the granting of certificates of qualifications; (*e*) The establishment of such a status of the medical profession in Canada as shall insure recognition thereof in the United Kingdom, and enable Canadian practitioners to acquire the right to registration under the acts of the Imperial Parliament known as the "medical acts." The whole act is lengthy, consisting of some twenty provisions, but the chief aim in passing such a law is to raise the standard of medical education throughout Canada to a uniformly high one, so that a Canadian medical qualification will stand on an equal plane to that of Great Britain, and will be thus recognized.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 4, 1902:

	Cases.	Deaths.
Measles	47	1
Diphtheria and croup	239	26
Scarlet fever	100	8
Smallpox	1	..
Varicella	14	..
Tuberculosis	195	113
Typhoid fever	190	24
Cerebrospinal meningitis	..	..

Some Statistics Regarding Heredity.—Dr. William C. Krauss of Buffalo, N. Y., published recently, in the *American Journal of Insanity*, a study of the statistics of the New York State hospitals, with respect to the importance of heredity in the causation of nervous and mental diseases, and commences by remarking that although this fact was known and appreciated by writers on these subjects for ages, the mode of transmissibility remains to-day as much of a secret as when the doctrine was first promulgated. Dr Krauss thinks that the diagnostic value of an hereditary tendency to insanity depends largely on its degree. Thus the insanity of one parent would indicate a less degree of predisposition than that of one parent and an uncle, or still less than that of a parent and a grand-parent, or of both parents. Again, the insanity of a parent and a grand-parent with an uncle or an aunt in the same line may be held to indicate a stronger predisposition than even the insanity of both parents. The significance of the insanity of parents will depend, to a large extent, upon the period of its onset. The insanity of a parent occurring after the birth of a child, if it arose from a cause adequate to excite it, without previous predisposition, would be held, of course, as of no value in the formation of an hereditary tendency.

The insanity of relatives further removed than parents, uncles, and aunts, brothers and sisters and first cousins, is not worth anything, except in corroboration of nearer and weightier facts. But the influence of other related diseases to insanity occurring in those near akin, such as eccentricity, alcoholism, epilepsy, hysteria, hypochondriasis, vicious or criminal tendencies, etc., may be of great import. The following facts are gathered from a consideration of statistics collected from thirteen New York State hospitals. Percentage of cases showing heredity, 1899–1900, 25.8; since 1888, 24.5. Percentage showing heredity, exclusive of unascertained cases, 1899–1900, 36.6; since 1888, 30.7. Percentage showing no hereditary tendency, exclusive of unascertained cases, 1899–1900, 63.3; since 1888, 59.8. Total number of cases admitted, 1899–1900, 6,361, since 1888, 61,257. Total number of hereditary cases, 1899–1900, 1,202; since 1888, 14,526. The hospital showing the highest percentage of heredity of the whole number for the year 1895–1896 was the Matteawan Hospital, with a percentage of 57.1; for the year 1898–1899, the St. Lawrence Hospital, with a percentage of 41.6; for the year 1899–1900, the Binghamton Hospital, with a percentage of 30.2, and since 1888, the St. Lawrence Hospital, with a percentage of 33.8. In the census returns of 1890, of 70,340 insane studied with reference to heredity, 22,077, or 31.38 per cent., had insane relatives: the number having insane fathers was 2,531; insane mothers, 3,159, insane grandfathers, 784; insane grandmothers, 810; insane uncles, 2,408; insane aunts, 2,034; insane brothers, 3,630; insane sisters, 3,704; insane sons, 465; insane daughters, 480 (Kellogg). The transmission of heredity through the maternal branch is greater than through the paternal, being 372, as compared with 335 for the year 1895–1896; 420 to 340 for the year 1898–1899, 450 to 320 for the year 1899–1900, and 4,261 to 3,608 since 1888. It is a noteworthy fact that the reports of the New York State Hospital show that maternal transmission is increasing rapidly over paternal transmission as shown by comparison of the figures given for the years 1895–1896 and 1899–1900. Dr Krauss concludes his interesting study by pointing out that heredity is found to be just as strongly represented in the various neuroses as was found for the psychoses.

The "Light Cure" at Copenhagen.—In the *American Review of Reviews* for October is an article on Professor Finsen and his work. The account is written in a popular style, so as to make it comprehensible to lay readers, but at the same time, some of the descriptions of the apparatus should prove of interest to the scientific medical man. A part of the description reads as follows: "While Professor Finsen began his experiments with sunlight, and still employs the natural rays when weather conditions permit, yet the inconstancy of the northern sun has made it necessary to treat the majority of cases with electric light. For this reason it is more to the point to dwell, first, on the construction of the electric-light apparatus, which, with their power of 20,000 candles each, are, nevertheless, so designed that the intense heat developed becomes nil as the tremendous glare strikes directly on the patient's face. It is this ability to utilize the chemical action of the concentrated light, and exclude the heat-giving quantity, which makes the observer look on in mute wonder. The concentration apparatus consists of quartz lenses, framed in two brass tubes which can be moved, the one into the other, like two pieces of a telescope. Lenses of quartz are used because this material, in a far higher degree than glass, allows the ultraviolet rays of the shortest wave length to pass through. The apparatus for the concentration of sunlight, however, may be made of glass, since all the ultraviolet rays here have longer wave lengths. In that part of the electric apparatus which faces the arc lamp two lenses are inserted. After passing from the lamp the divergent rays are here concentrated, and then they pass through the brass tubes, at the distant end of which they meet again with two lenses of quartz. Between these two latter lenses there is distilled water, which cools the light by absorbing the intensely heating ultrared rays, but does not impair the blue, violet, and ultraviolet ones. Four such apparatus for light concentration are fixed around each arc lamp, the whole supported from the ceiling. As far as the curative implement is concerned, everything has been done now to rob the light rays of their heat. But still the light is too hot to be turned on the skin without working injury. Therefore, since the light itself can be cooled off no further, the skin must be subjected to a cooling process. This is obtained through a little contrivance that consists of a brass ring which is closed at both ends with quartz plates. The brass ring also contains a small tube for the admission of running water and another tube to carry it off. By means of elastic bands the ring is now forced against that part of the skin which is to be treated. The cold, running water cools it off to such a degree that the skin can now stand a concentration of rays with a heating force sufficient to set fire to a piece of wool. This little apparatus has the additional function that it removes the blood from that part of the skin against which the ring presses. This very essential feature makes it possible for the chemical light rays to penetrate where otherwise the blood would absorb these rays. The water is carried through a rubber tube from a reservoir above, and after passing through the pressure apparatus finds its outlet beneath the floor."

Increasing Age of Population.—The Census Bureau has issued a statement showing the increasing age of the population from decade to decade. The median age of the total population in 1900 was 22.8 as compared with 21.9 in 1890. The median age of the white population in the last census year was 23.4, and the colored was 19.7; while in 1890 that of the white population was 22.4 and the colored 18.3. The report shows that there was an increase in the median age of the white population in each decade from 1810 to 1890, amounting in the ninety years to 7.4 years.

The Prognostic Significance of Hæmatemesis.—W. Janowski has found that the most reliable test for the presence of blood in vomitus is Weber's. This is carried out by shaking the suspected material in a test tube with one-third of its volume of acetic acid and the same amount of ether. The ether is then allowed to rise to the surface and a couple of cubic centimeters are decanted. To this five to ten drops of tr. guaiac and fifteen to twenty drops of old ol. terebinth. are added. The presence of blood is indicated by the appearance of a bluish-violet color, which may be made more evident by the addition of a few drops of chloroform. When the blood has entered the stomach by flowing into it from above from the upper-air passages, the prognosis naturally depends on the nature of the primary lesion. But, as this is usually of gravity (general sepsis, endocarditis, nephritis, scurvy, tuberculosis, etc.), hæmatemesis under these conditions is to be regarded as one of the most serious symptoms. In acute intoxications the bloody appearance of the vomitus is not necessarily of prognostic significance, for it simply indicates a certain degree of corrosion of the mucous membranes. The obstinate, painful vomiting of dark chocolate-colored, often fetid, material, however, is of grave import, and points to deep and extensive gastric ulceration with impending perforation or great danger of subsequent stricture. In gastric ulcer even small and infrequent hemorrhages do not permit a definite prognosis for more than a short time and never regarding permanent cure. In carcinoma hæmatemesis has the most sinister significance, as it appears in the later stages when surgical intervention is no longer feasible. Accompanying the perforation of stomach or duodenum, this symptom portends a fatal result unless adhesions are present, as even surgery usually is too late. In cirrhosis the prognosis depends on whether the bleeding comes from a capillary plexus or is the result of the rupture of a larger vein, in which case death may follow. When hæmatemesis is a symptom of pylephlebitis the prognosis is unfavorable, as it also is in wounds of the liver, pancreas, or stomach, and in aneurysm of the cœliac axis. In yellow fever the bloody vomit causes increased anxiety only when long continued, while its early cessation is a hopeful omen. In the plague hæmatemesis occurs only in the severest cases, which is also true in peritonitis following sepsis. Following laparotomies, and in endocarditis, its appearance usually is a forerunner of speedy death, and it is an unfavorable sign in acute yellow atrophy of the liver, leukæmia, and scurvy. In intestinal obstruction and peritonitis it is an evidence of sepsis. In chlorosis the prognosis is not made more grave by it, and in hysteria and gastric crises its importance depends on its frequency and severity, as hysterical women sometimes bleed often and freely without serious detriment to their general health. In the new-born hæmatemesis is accompanied by a mortality of from 50 to 60 per cent.—*Zeitschrift fur klinische Medicin.*

Alcohol as Food or Poison.—Professor Kassowitz has published, in a recent issue of the *Archiv fur die gesammte Physiologie*, the results of investigations and experiments carried out by him in his effort to settle the much-vexed question as to whether alcohol is a nutritive substance or not. A certain number of dogs were given definite amounts of food and required to take a stated amount of exercise each day. The dogs were placed on a running machine, and the distance run by each dog was recorded. During the first week that the dog that was given food without alcohol ran 10.888 kilometers per hour, while its mate, sustained by the same kind of food, with the addition of alcohol, ran only 7.847 kilometers per hour and showed a loss of weight at the end of the week, the first dog having gained in weight. During the following week the work was reduced on account of warm weather. The first dog ran 7.794 kilometers per hour, the second dog, given alcohol, 6.901 kilometers.

Several other experiments of a like nature were carried out, and it was found that the results were uniformly against the alcohol-fed dog, both as to the amount of work accomplished and changes in weight. The author thinks that the idea of alcohol having a nutritive value comes from the supposition that a part of the food may be oxidized directly without first taking part in the building up of protoplasmic substance. He is of the opinion that no food material can be used in the body without first being converted into protoplasm. Since alcohol, as a stimulating and poisonous substance, destroys the highly complex and unstable protoplasmic molecule, it cannot at the same time be assimilated by it, consequently it cannot act as food and poison simultaneously. After a comparatively short period, alcohol paralyzes the center of innervation for the muscles and, therefore, by diminishing the amount of muscular action, the secretion of carbonic acid is lessened. This diminished secretion, consequently, means no saving of the tissues of the body, but it is a direct result of the poisonous action of alcohol. Kassowitz is convinced that under no conditions can alcohol act in a nutritive manner.

Nothing New, Etc.—In these columns we have shown a number of times that many remedies and methods, now considered new and modern, were known and used hundreds of years ago.

Dr. Charles Francis now calls attention to the fact that saline injections in cholera were used during Sir James Paget's apprenticeship.—*Merck's Archives.*

Health Reports.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 4, 1902:

STATISTICAL REPORT ON CREOSOTE IN PNEUMONIA.

BY I. L. VAN ZANDT, M.D.,
FT. WORTH, TEX.

EARLY in last March I sent to many medical journals, and to a few individuals, a circular asking those who had used creosote or carbonate of creosote in the treatment of pneumonia to send me, in April, on a postal card the number of cases treated and the number of deaths; also yes or no to the following questions: (1) Do you believe creosote ever aborts pneumonia? (2) Do you believe the majority of cases are mitigated by it? (3) Have you ever found cases which, having plenty of time, were entirely uninfluenced by it?

In response I have received more than seventy letters and cards and five verbal reports. These came from Ontario, Mexico, Honduras, twenty-two States, and the Indian Territory.

This shows that the creosote treatment has had a widely extended trial. The accompanying table

NAME.	POST OFFICE.	CASES.	DEATHS.	QUESTIONS. 1	QUESTIONS. 2	QUESTIONS. 3	REMARKS.
Jno. W. McCullough	Alliston, Ont	2	0				
Hitchcock and Ferrell	Brookwood, Ala	11	0		Yes.	No	Aged eighty-four and forty. Both improved four or five days, when other lung became involved, and both died. Query: Was remedy omitted?
G. W. Bailey	Elizabeth, N. J.	2	2				
K. Lowder Reed	Atlanta, Ga.	1	0			Yes.	
L. S. Green	Elma, Miss.	2	0				
E. B Gilbert	Abilene, Tex	2	0	Yes.	Yes.		
J. H. Alexander	Meridian, Tex	18	1	Yes.	Yes.	No.	In fatal case, by second visit 104 to 99. A second chill followed, when the stomach, "a very catarrhal one," rejected everything for seven days.
R. S Lipscomb	Grapevine, Tex.	26	1	Yes.	Yes.	Yes.	
L. W. Hollis	Abilene, Tex	26	0	Yes.	Yes.	Yes.	
Fred. B. Johnston	Anderson, Tex.	27	1		Yes.	Yes.	Aged seventy-two. Complicated with heart trouble.
W. Penn Buck	Lansdowne, Pa.	9	0		Yes.	Yes.	
Leonard Weber	New York City	21	2	Yes.	Yes.	Yes.	Fatal cases complicated with other diseases.
L. E. Maker	Sibley, Ia.	10	0		Yes.	No.	
S. E. Sanchez	Barwick, Ga	19	1	Yes	Yes.	No.	
J. H. Burnett	Kopperl, Tex	8	0	Yes.	Yes.	Yes.	
Geo. H. Sanborn	Henniken, N. H	22	1	Yes.	Yes.	No.	
E. W. Hawthorne	Gypsum, Ind. Ty.	5	1	No	No.	Yes.	
A. A. Blassingame	Chisholm, Tex.	13	3	Yes	Yes.	Yes.	One sixty-seven years old, one complicated with measles, and one with obstructed bowel.
J. S. Cleland	Swanwick, Ills.	6	0	Yes.	Yes.	No.	
J. W. Carey	Whitesboro, Tex.	18	0	Yes.	Yes.	No.	
A. A Stafford	Alameda, Cal.	2	0				
J. A. Gracey	Waxahachie, Tex.	30	1	Yes.	Yes.	Yes.	Double hypostatic pneumonia after five weeks typhoid fever.
W H. Davis	Arlington, Tex	72	1	Yes.	Yes.	No.	
J. D. Croom	Maxton, N. C.	6	0	No.	Yes	Yes.	
H. H Stamper	Compton, Ky.	12	0	No.	Yes.	No.	
D. Gardner	Lehigh, Ind. Ty	22	4		Yes.		Two were "old men," pneumonia developing after seven to twelve days of "Grippe."
J. T. Selman	Joshua, Tex.	7	0	Yes.	Yes.	No.	
W. J. Chapman	Lake City, Miss.	4	0	No.	Yes.	No.	
A. M. Elnore	Dallas, Tex.	4	0	Yes.	Yes.	No.	
M. N. Due	Birmingham, Ala.	18	0	Yes.	Yes.	No.	
W. D. Lipscomb	Grapevine, Tex.	36	4		Yes.		One died five days after subsidence of fever from purpuric hemorrhage. One developed meningitis early in attack; One, bed-ridden five years, had attack following cholera morbus. One uncomplicated.
O. N. Schudde	Iberia, Mo.	24	1	Yes.	Yes.	Yes	
H. C. Whitehead	Ft. Worth, Tex.	5	0	Yes.	Yes.	No.	
F M. Hale	Crews, Tex.	10	0	Yes.	Yes.	No.	
V. P. Armstrong	Dallas, Tex.	11	0	Yes.	Yes.	No.	
I. A. Langston	Ross, Tex.	18	1	Yes.	Yes.	No.	The one death, railroad section hand; disease far advanced when called.
Frank Peak	Pratt, Kan.	1	1				
W. R. Howard	Ft. Worth, Tex.	122	4	Yes.	Yes.	No.	One with cerebral meningitis. Two—seventy three and eighty-three—would not stay in bed. One, aged three, following dysentery and whooping cough.
J. S. Berkman	Rochester, N. Y	4	0	Yes.	Yes.	No.	
P. F. Rice	Gaines Station, Mich.	1	0				
E. B. Tefft	New Rochelle, N. Y.	20	1	No.	Yes.	Yes.	
E. S. Lain	Bolivar, Tex.	13	0	Yes.	Yes	No.	From January 27, treated twelve cases without creosote, two deaths. Thirteen with creosote, no deaths.
L. C. Rouglin	Atlanta, Ga.	4	0	Yes.	Yes.	No.	
H. W. Cummings	Hearne, Tex.	45	2	No.	Yes.	Yes.	One, a very old man, died suddenly on fifth day after an attempt to get up.
E. P. Hall	Polytechnic College, Tex.	45	0	Yes	Yes.	Yes.	
J. W. Starr	Lacona, Ia.	5	0	Yes.	Yes.		
B. H. Brodnax	Brodnax, La.	9	0	No.	Yes.	No.	
W. A. Morton	Paradise, Tex.	25	1	Yes.	Yes.	Yes.	In fatal case lung cleared up, but patient took on low grade of fever, of typhoid type, duration thirty days
F. M. Vessels	Brewer, Mo.	5	2	No.	No.	Yes.	
J. B. McMackin	Wayland Springs, Tenn.	27	1	Yes.	Yes.	No.	
W. E. Redford	Boyd, Tex.	12	1				
Hill & Johnson	Reyno, Ark.	7	0	Yes.	Yes.	No.	Alcoholic, died from cerebrospinal meningitis Aspirated fluid, showing by culture pure pneumococcus.
O. Mallet	Troy, N. Y.	11	1	No.	Yes.	No.	
W. B. Pullen	Jacksonville, Tex.	15	0	Yes.	Yes.	Yes.	
Yates & Yates	Ander, Tex.	25	0	Yes	Yes.	No.	
Henry A. Kurth	Schenectady, N. Y.	1	1				
W. C. Brown	Britton, Tex.	8	0	Yes.	Yes.	Yes.	
J. T. Moore	Minneapolis, Minn.	8	1	Yes.	Yes.	No.	Fatal case, aged eighty-four.
H. S. Gully	Meridian, Miss.	6	1	Yes.	Yes.	No.	
W. A. Adams	Ft. Worth, Tex.	32	0	Yes.	Yes.	No.	
W. E. Van Zant	Mandeville, La.	1	0				
Jno. L. Scales	Alden Bridge, La.	9	1	No.	Yes.	Yes.	
M. H. Cravens	Arlington, Tex.	51	3	Yes.			One fatal case, was a chronic alcoholic
Anonymous	Stetson, Me.	14	0	No.	Yes.	Yes.	
Wilson O. Bridges	Omaha, Neb.	11	1		Yes.	No.	Used "creosote products." Fatal, double pneumonia with asthma.
J. D. Pettet	Mound Valley, Kan.	8	0		Yes.		
J. P. Gaston	Gilbertsboro, Ala.	6	0	No.	Yes.	No.	
W. H. Thomson	New York City	18	1				Taken from MEDICAL RECORD.
*Ignacio V. Johnson	Vera Cruz, Mex.	12	4	No.	Yes.	No.	
F. T. B. Fest	Tegucigalpa, Honduras	12	3	No.	Yes.		
W. P. Sipe	Cripple Creek, Col.	8	1	No.	Yes.	Yes.	Dissipated man, complicated with pericarditis. Normal mortality very high in this altitude.

---

*Since completing the table I have received a letter from Dr. I. V. Johnson, Vera Cruz, Mex., from which I abstract as follows: "Pneumonia is more fatal here than in other towns." All these cases were very poor, some alcoholic, all ignorant, and most in previous bad health. Of fatal cases one was a double pneumonia, with little hope from beginning; one complicated with abortion, and "did not take regularly the drugs prescribed;" two were bottle-fed babies, and in both, attack followed measles and whooping cough. His dose had been smaller than recommended in reprint I had sent him gives the results of treatment, and the estimate in which the remedy is held.

I am gratified that so many have been moved to send reports, but yet am disappointed at not receiving reports from some localities in which I knew the treatment was in use. A few of these letters gave no numbers but opinions only. Two of these express adverse opinions, while the others enthusiastically advocate the treatment—two of the writers, however, having used guaiacol carbonate. One writer said he had used the creosote carbonate in approximately sixty cases, with no death except where there was "organic heart complication," but, unfortunately, he did not say how many had the "complication," so his report had to be left out.

Some of the reporters are recent converts, while others, as Dr. Howard, have used the treatment for a long time. His report covers seven years. The diagnosis of each case having been written on his ledger during or soon after the treatment.

It will be noted that I have not put my own work in the table. For this there are two reasons; first, I have constituted myself the "advocate" and do not wish to testify in my own behalf; second, I kept no clinical records, and did not think I could go back over my account books for eight years and pick out the cases of pneumonia.

I most heartily thank all who have sent reports, whether favorable or unfavorable; also all journals which were kind enough to publish my circular.

To the first question, thirty-seven, reporting 762 cases, say "yes"; fifteen, reporting 187, say "no"; and nineteen, reporting 177, fail to answer. Those reporting, a little more than two-thirds of the cases, assert the abortive effects of creosote.

To the second question, fifty-seven, reporting 1,022 cases, answer "yes"; two, reporting ten cases, say "no"; the remainder fail to answer.

To the third, twenty-three say "yes"; thirty-one, "no"; and sixteen fail to answer.

These answers furnish strong confirmation of my conclusions given in a former paper, viz., "A large per cent. of pneumonic cases are cut short or aborted, almost all the rest are mitigated, and the remainder, a very small per cent., are not at all affected by the remedy."

The figures of Dr. W. H. Thomson, near the close of the table, merit special attention. These cases were treated in Roosevelt Hospital. The loss was one in eighteen, or about 5.5 per cent. I have lately seen a condensed report for five years from this institution, giving an average death rate of 35.6 per cent. The contrast is striking.

Summing up the whole, we find 1,130 cases and fifty-six deaths, a little less than 5 per cent., but this is very much mitigated by report of complications under "Remarks." Contrasting this with the ordinarily recognized death rate, 25 per cent., we see in each 100 cases a saving of twenty lives, or 226 in 1,130.

This may be made even more striking by taking some official figures. The Registrar General of England, in 1900, published that the deaths from pneumonia in one year in the United Kingdom were 30,000 (almost as many as from typhoid fever, scarlet fever, measles, whooping cough, and diphtheria). This was presumably 25 per cent. of the cases, and according to our table, four-fifths, or 24,000, ought not to have died.

Again, taking the figures of our own last census, we find that 105,971 died in one year from pneumonia. If this is 25 per cent. of the attacks, four-fifths of these, or 84,774, ought not to have died.

In the light of these figures, and my own observations for more than eight years, I again venture "to express the opinion that the use of creosote or carbonate of creosote in the treatment of acute pulmonary inflammations is one of the greatest life saving discoveries of the nineteenth century."

THE RESULTS OF TREATMENT OF LARYNGEAL CANCER BY MEANS OF THE X-RAY.*

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

The suggestion that the *x*-ray might possibly prove an effective remedy for malignant disease has aroused universal attention. During the past year series of experiments have been undertaken in all leading scientific centers, and large numbers of observations have been made. The knowledge of this has not been slow in reaching the general public, and the victims of cancer are clamoring to know whether or not the new remedy is an assured success. Their anxiety is natural in view of the character of malignant disease itself, and also in view of the acknowledged danger of disaster from loss of time spent in useless experimentation when, as far as we now know, early radical operation is needed in order to secure even a fair chance of success.

What the *x*-ray itself is, or is not, how it should be applied, and what has been accomplished by it in other fields, it is not my purpose to discuss.

During the past six months we have been repeatedly importuned by sufferers from laryngeal cancer as to whether, in their cases, the use of the *x*-ray would be likely to effect a cure. The answer has always been that the study of this subject was in its infancy, and that no reliable information concerning it was at hand. Feeling that the importance of the subject warranted the most careful attention, and that we should try to discover as speedily as possible whether the method could be recommended or not, I have felt justified in presenting a few notes which will suggest the actual position of the question at the present time. In order to gain the necessary information I have studied recent literature for reports of cases, have attended several meetings at which the subject was discussed, and have personally interviewed a number of leading experimenters. I regret to report that, to the best of my knowledge, up to the present time, not a single case of carcinoma of the larynx has been cured by the *x*-ray. Of several large institutions in New York City at which the *x*-ray is being used upon malignant cases in general, but one has had cases of laryngeal cancer. Here four cases have been treated, two, as I understand, with unsatisfactory results, and two, still under treatment, showing some signs of improvement, but far from being cured.

Dr. Wm. J. Morton has treated for me a case of advanced malignant disease of the throat, originating in the larynx, with interesting results as to the effect of the treatment upon the mass of the growth. The patient died, however, from chronic Bright's disease after about twenty applications of the *x*-ray. In a case of cancer of the tonsil and lateral wall of the pharynx, shown me by Dr. Morton, the results thus far seem to be excellent.

During the past three months this subject has been presented and fully discussed at three largely attended meetings in New York City. Both meetings called out an unusually full representation of those practically interested, and included leading experts from Boston, New York, Brooklyn, and Philadelphia. Not a case of cancer of the larynx was reported. I am unable to find that any cases have been reported from Chicago.

---

*Read at the twenty-fourth annual meeting of the American Laryngological Association, Boston.

Reviewing the literature of the subject, Pusey (*Journal of the American Medical Association*, April 12, 1902) reports a large series of cases, in none of which the larynx was involved. Dr. Wm. B. Coley writes to me (May 19, 1902), "I have tried to keep track of everything that has been published about the *x*-ray treatment of cancer, but thus far have not run across anything directly bearing upon laryngeal cancer. However, I do not see why the good results obtained in other localities should not be duplicated in the larynx."

Dr. Morton tells me that he is treating at present one epithelioma of the tonsil and lateral wall of the pharynx; one of the superior maxillary region following extraction of molar teeth; one of the cheek, and one of the tongue. Improvement in all of these cases is taking place.

From the meager and fragmentary details which I have been able to secure, it would appear that no positive deductions as to the value of the *x*-ray in laryngeal cancer can be made until the method has been tried upon a larger number of cases than up to the present time have been treated by it, and that a considerable period of time must elapse in the study of a given case before it can be pronounced cured. In the general results thus far obtained, such diseases as lupus and various other lesions of the surface have responded more satisfactorily than have deeply-seated malignant growths. This appears to be true of laryngeal cancer, in which the effects of the *x*-ray have apparently been less satisfactory than in some other directions.

In answer to the question "should the *x*-ray be resorted to for the treatment of cancer of the larynx," it is fair to say that with regard to inoperable cases, since much relief has been afforded in general cases of malignant disease and in the relatively few cases of cancer of the neck and throat in which it has been applied, the victim of advanced laryngeal cancer should be allowed the benefit of it.

On the other hand, in early cases of laryngeal cancer it is a grave question whether any time whatever should be lost in experimentation. The universal opinion of the day is to the effect that Butlin's plea for early radical operation is correct, and that nothing else offers even a fair chance of safety. On the other hand, it is stated that the benefits of the *x*-ray treatment are likely to make themselves quickly apparent, and that a fair trial of it might be made within a period of two weeks. This being true, we may safely conclude that, in the average case, where the progress of the disease was not rapid, and where a few days would have to elapse in any event between the time that the diagnosis of cancer was established, and the operation for its removal actually performed, it would be entirely justifiable to submit the patient to treatment by the *x*-ray. The same principle is already observed in the administration of iodide of potassium for the purpose of eliminating the possibility of the local disease being due to syphilis. It is certainly not going too far to assert that it should also be carried out with the *x*-ray. That the method is a specific cure for cancer has not yet been proved. Without question, however, it possesses extraordinary possibilities which cannot long remain in doubt. What is now needed is the largest possible series of carefully reported cases and an allowance of time sufficient to prove that the new treatment is capable of complete and lasting success.

CASE.—S. C., aged sixty-five, widower. Had syphilis twenty years ago. Has chronic nephritis. Is rheumatic. Voice became hoarse in February, 1901. Consulted me in November, 1901. At this time there was a large mass, apparently epitheliomatous, springing from the right side of the larynx. There was much infiltration of the posterior commissure and beginning involvement of the opposite side of the larynx. The glands of the neck were involved on both sides, as was the interior part of the lateral wall of the pharynx. The case was clearly inoperable, on account of the wide distribution of the disease, the condition of the kidneys, and the age of the patient. In order to eliminate the possibility of the lesions being specific, the patient was placed upon the iodide of potassium in moderate doses. The result of this was promptly disastrous, for within a few days he developed sudden œdema of the larynx with urgent dyspnœa, and his life was saved only by instant tracheotomy. During the winter the growth in the larynx and neck increased enormously in size. In March he was placed under the care of Dr. Morton for treatment with the *x*-ray. He submitted to about eighteen exposures. After the first few treatments the growth seemed less tense and began to soften at its middle and to harden at one end. Soon the entire contour of the growth seemed to change. Later it seemed that the mass was breaking up, as there was a distinct attempt at the separation of one segment of it from the other. At this period treatment had to be abandoned, and the patient shortly afterward died from Bright's disease. There appeared to be no doubt that the mass became smaller and softer after about two weeks' treatment, and that the patient would have been benefited had his general condition not been so unfavorable.

1 EAST THIRTY-THIRD STREET.

VARICOCELE.*

By CHARLES CHASSAIGNAC, M.D.,
NEW ORLEANS, LA.

PROFESSOR OF GENITOURINARY AND RECTAL DISEASES, AND PRESIDENT OF THE NEW ORLEANS POLYCLINIC; EDITOR OF THE "NEW ORLEANS MEDICAL AND SURGICAL JOURNAL," ETC.

THE term varicocele, etymologically speaking, signifies a tumor due to dilated veins, without any reference to its location. Actually, it is taken to mean a varicose condition of the plexus of veins accompanying and surrounding the spermatic cord.

Anatomical Characters.—For a proper understanding of the various phases of the subject, it may be well to review the normal and pathological anatomy of the parts involved. Proceeding from the testicle, the spermatic veins in their upward course become convoluted, and form what is called the spermatic or pampiniform plexus, in and around the spermatic cord. The veins then converge into two or more branches, which unite to form the spermatic vein, at some point between the level of the external abdominal ring and the middle of the crest of the ilium. This vein on the right side empties into the vena cava at an acute angle and on the left into the renal vein at a right angle, after passing beneath the sigmoid flexure. The left vein is generally longer and larger than the right, and receives branches, usually two in number, from the descending colon. The spermatic veins lie in loose tissue, which afford them practically no support.

In varicocele some or all of these veins are tortuous and dilated; they are usually increased in number, and their walls are thicker than normal, all of which leads to a diminution in their elasticity and contractility. When cut, they often remain gaping in the manner of arteries. It is chiefly in the middle tunic that the connective tissue is increased apparently from a slight degree of chronic inflammation. The swelling produced by varicocele is usually conical in shape, the base being at the testicle, and the apex ending in the inguinal canal.

---

* Read before the Louisiana State Medical Society, at Shreveport.

The testicle in pronounced varicocele is likely to be more or less affected. It is apt to be soft, flabby, somewhat shrunken, insensitive, though at other times tender, and sometimes even atrophied. It is a debated point whether the atrophy is a result or a coincidence, also whether it is a lack of development rather than a true shrinkage. Authorities galore could be quoted on either side. There is no doubt that atrophy of the testicle, not preceded by gonorrhœal or syphilitic orchitis, accompanies varicocele frequently enough to show that there is a relation between the two. I have seen several instances of the kind, and it seems to me rational to suppose that the interference with circulation, due to impeded outflow and to pressure on the gland, can lead either to imperfect development or to actual shrinkage from innutrition, the difference in the process being doubtless due to the age at which the affection becomes sufficiently pronounced, and to the extent of the trouble.

The scrotum becomes relaxed, elongated, and its structure thinner and less elastic; its veins also are often, though not always, varicose, sometimes to a pronounced degree.

Causes.—There is a wide difference in the ideas entertained regarding the relative importance of constitutional and of local conditions as causes of varicocele.

Considering the period of life at which this affection generally begins, to be referred to later, a careful study of the various views on the subject leads to the opinion that constitutional and even congenital lack of vascular tone is its predisposing and sometimes all-sufficient cause; that, for anatomic reasons, this weakness is shown earlier and more readily in the spermatic veins; and that, on account of anatomic differences between the sides, it develops more frequently on the left.

In individuals with the predisposition above specified, the exciting causes may be mentioned as (1) Chronic constipation, producing prolonged pressure on the left spermatic vein by the full colon; (2) Occupations demanding continuous and prolonged standing, by keeping the veins distended; (3) Sudden and violent efforts or straining; (4) Frequent and long-continued sexual excitement, not followed by relief, leading to more or less constant congestion of the parts; (5) Persistent cough and dyspnœa. None of these causes, or perhaps no combination of them would produce varicocele in an individual blessed with a perfect vascular system, but any one of them might be sufficient to accentuate and bring out a pre-existing lack of tone in the walls of the spermatic veins.

Heredity is considered an important factor by some, and dismissed as a cause by others. Masturbation and sexual excess are often mentioned in the books as causes of this affection, but the concensus of opinion to-day seems to be that they are, on the contrary, the reflex result of irritation of the testicle, produced by the varicocele at the time of life when the generative system is most easily excited. Guyon reports having observed several cases in which the disease was due to pressure produced by a tumor of the kidney.

Frequency.—Statistics and estimates as to the prevalence of varicocele vary to an astonishing degree, all the way from 2 to 75 per cent. This can be explained only in two ways: by the difference in the degree of varicosity deemed requisite to be considered pathologic and by the various classes and ages of the subjects examined by different observers, respectively. Only when the veins are enlarged sufficiently to be visible, palpable, and the cause of some relaxation of the scrotum, should the condition be considered a diseased one; also all types and classes of men should be included in the statistics if we attempt to determine the general frequency of the condition. Henry found only a little over 2 per cent. affected in a large number of men examined for appointment on the police. Horteloup found 2½ per cent. in nearly two thousand examinations. Curling reports about the same percentage in 166,317 young recruits examined in ten years for England and Ireland. Lydston's observations show that "5 per cent. of male adults" have a moderate degree of varicocele. Bennett claims that, taking all classes into consideration, about 7 per cent. have sufficient enlargement for it to be called varicocele. Keyes states that the "common estimate" of the frequency of the trouble is 10 per cent. Humphry, too, estimates that the disease occurs in 10 per cent. of males. Senn examined nearly 10,000 recruits during the Spanish-American war, and found over 21 per cent. with different degrees of spermatic varicosity. Landouzy, long ago, said that 60 per cent. of adult males were affected. Wertenbaker, who has examined recruits for the life-saving service during fourteen years, concludes that a *slight* degree of varicocele exists in at least 75 per cent. of men.

I have recently examined, with the aid of Dr. Paul Gelpi, one of my assistants, 316 patients in my ward and clinics at the Charity Hospital, at the Polyclinic, and at my office. Of this number forty-seven were found to have varicocele, twenty-eight slightly and nineteen to a pronounced extent; forty-four had it on the left side, two on both sides, and one on the right side. This would show a prevalence in almost 15 per cent. of the men examined, in whom were included men of all ages, colors, and conditions. Still, among those seen, there was a preponderance of young men; it must also be taken into account that the majority were genitourinary patients. The conclusion, to my mind, is that 15 per cent. is yet a little high, and that the "common estimate" of the frequency of the trouble, mentioned by Keyes, is very nearly correct; namely, 10 per cent.

Relative Frequency of Side Involved.—While here again there are marked differences in the figures presented by various observers, there is unanimity in declaring that the left side only is involved in the large majority of cases (80 to 90 per cent.); both sides are affected in about two-thirds of the remaining cases; those in which the right side alone is involved are the least in number, probably about 5 per cent. Even when the right side is included in the process, it is usually in a less pronounced degree and gives less trouble. For instance, Curling mentions that in more than 120 patients operated upon for this disease by Breschet, in only one was it located on the right side, and Keyes has never operated on that side. I have seen several situated on the right side, but none giving rise to symptoms justifying operation.

This marked preponderance on the left side is easily explained by the anatomic differences already enumerated: (1) The acuteness of the angle of junction of the left spermatic vein with the renal. (2) The greater length of the left vein, owing to the lower position of the left testicle. (3) The relation of the left vein with the sigmoid flexure, exposin the former to pressure from fecal matter during th intervals between defecations. Other reasons ar sometimes given, such as the tendency of men to stand more on the left foot, and the habit of "wearing" on the left side, but my opinion is that very little importance need attach to any but the anatomic differences. That the predisposition is much greater on the left side is further evidenced by the fact that in acute cases, produced by sudden strain, the disease almost always develops on that side.

Age of Prevalence.—Varicocele is met with chiefly in the young. It has been seen in boys under ten years of age, and Bennett mentions one case of marked varicocele in a boy of four years, demonstrated at post-mortem. Over half the cases are found at from fifteen to twenty-five years of age and few in men over thirty-five. On the other hand, it has been known to disappear after middle life.

Diagnosis.—It is generally easy to recognize uncomplicated varicocele, yet it is on record that the disease has been mistaken for hernia. It forms an irregular, convoluted tumor, somewhat pyramidal in shape, soft, doughy, compressible, and inelastic. It produces an elongated and relaxed condition of the scrotum; the walls of the latter are thinned, sometimes to the extent of assuming a dark-bluish hue, from the tortuous veins which show through. The feel of it is generally likened to that of a bundle of worms loose in a bag, and is very characteristic. When the person affected lies horizontally, the tumor disappears, as it usually does in inguinal hernia, but it does so more rapidly, and is not prevented from showing again, when the patient assumes an erect posture, by pressure applied at the external inguinal ring, as is the case in hernia; on the contrary, such pressure is apt to even increase the size of the tumor by interfering with circulation in the affected veins. As a rule, the tumor is painless, but it may be tender on pressure from a certain degree of phlebitis, which we have seen can sometimes be present. The swelling may increase on coughing, but the characteristic impulse of hernia is not felt. It is diminished in size by cold and increased by heat; also is more pronounced by bed-time than upon arising. It is, of course, dull on percussion.

When complicated, the varicocele becomes of secondary importance, the other ailment being nearly always that requiring attention and treatment.

Symptoms.—One of the most noteworthy points in connection with the subjective symptoms of varicocele is that their intensity does not correspond with that of the disease. Often a small varicocele will produce pronounced suffering, while as frequently a large one will cause little annoyance. Everything else being equal, young patients complain more of this condition than the middle-aged or old. The natural sensitiveness of the testicle, and the association of its nerves with the sympathetic system, explain why and how local and general disturbance may be expected. For convenience of study, we can divide the effects of varicocele into mechanical, reflex, and mental.

The Mechanical.—From the volume of blood dammed back in the veins involved, a sensation of weight and dragging is produced in the scrotum and along the cord. The pressure on the testicle may produce pain, tenderness, and neuralgia, although in advanced cases there may be a diminished sensitiveness. When the tumor is voluminous it gets in the way, interferes with the patient's activity, and even produces visible deformity. Cutaneous irritation is apt to develop from friction and moisture, frequently leading to pruritus, intertrigo, or eczema. I remember the case of a middle-aged man, in whom pruritus of the most persistent and distressing character was the chief symptom and who was promptly cured by operation

The Reflex.—Neuralgic pains of different kinds and different intensity are common. In the testicle itself they may be only slight, but, on the other hand, they may be most intense. Curling notes the fact that several operators have performed castration for their relief, at the request of the sufferers themselves. They may radiate to the penis, the perineum, the back, down the thighs, and have been known to include even gastralgia. Loss of tone in the sexual apparatus exists in most cases; this varies in degree from a slight diminution of sexual power to complete impotence. This loss of power can be due either, primarily, to the varicocele itself, or, secondarily, to the excesses and the seminal losses, which are also included in the reflex effects of the disease. Urethral neuralgia, vesical irritability, dyspepsia, and general malaise have been included in the list of subjective symptoms.

The Mental.—To the actual physical and the reflex symptoms of varicocele may be added the emotional. Disproportionate anxiety is characteristic of this disorder as well as of most of the sexual apparatus. Mental depression follows, to which hypochondriasis and neurasthenia are sometimes added. Even a suicidal impulse has been occasionally noted. There is no question but that the morbid tendencies resulting from this affection are frequently aggravated by quack advertisements, commercial medical literature, and the artful suggestions of the charlatan.

Prognosis.—If there is no intervention of any kind, the disease is apt to increase gradually from puberty to middle life, both as to physical and mental results, more or less rapidly, according to the occupation and mode of life of the patient. Occupations demanding violent efforts, or, on the other hand, very indolent habits, producing constipation and lack of vascular tone, favor the development of the affection; sexual excesses, and especially frequent ungratified sexual excitement, tend to aggravate the condition. After middle life varicocele gives much less trouble mentally and in a reflex way, while in the old it causes no inconvenience except mechanically, if quite large.

When palliative measures are carried out properly, the bad effects are overcome in a large proportion of cases, and there is no progress in the disease, provided an exciting cause does not continue to exist in a marked degree, and there is no morbidity on the part of the patient. Cases have been reported in which the disease disappeared after the patient had passed the age of thirty.

Radical treatment by means of any of the operations to be described, properly selected and performed, promises a positive removal of the abnormal physical condition. Even shrunken and undeveloped testicles have been known to grow and resume a natural state. Cessation of the reflex and mental phenomena also usually follows; in fact, a part of the benefit at times perhaps results from the moral effect of the operation. Yet it would be rash to give too positive an assurance of complete relief, as some of the neuralgic pains may occasionally persist. Especially must we be careful in reference to impotence, for we cannot be certain always that the lack or absence of sexual power may not be a coincidence, and be due to a separate and distinct cause. The possibility of the latter should be carefully studied, and suitable treatment of the accompanying or complicating ailment be promptly instituted.

Palliation.—In a large proportion of the milder forms of varicocele, palliative measures are sufficient. These consist: (1) In the removal of any exciting cause. The bowels must be carefully regulated; straining, heavy lifting, and constant standing must be abandoned; any existing cough should be relieved; sexual life must be regulated so that occasions for frequent ungratified desire may be avoided, as well as excesses of actual commission. (2) In toning up the general system, and especially the circulation. Systematic but gentle exercise, preferably out of doors; the daily use of the cold plunge or shower bath, followed by a brisk rub; the administration of iron, strychnia, and any other tonic indicated, or the use of bromides if there is much nervous excitability, will all prove beneficial. (3) In local applications. Bathing the scrotum in very hot or in cold salt water, morning and night; applying astringent lotions, such as the aqueous extract of witch-hazel or weak lead water, by causing contraction of the scrotum, affords some support and consequent comfort. (4) In wearing a suspensory. This should be light, though strong enough to be firm, and by all means well-fitting; it should relieve the testicle and scrotum of all weight, hence the medical adviser should see that it is carefully adjusted; it should be worn constantly except during rest in bed, the local baths already mentioned being resorted to when it is removed and before it is again applied; the patient should possess two at a time, so that they can be changed daily, not only in order to be cleaned when necessary, but that they may not become stretched as readily. (5) The patient's mental annoyance and exaggerated apprehensions must be allayed by sensible advice and an adequate explanation of physiologic and hygienic laws relevant to the subject.

Indications for Operation.—We should have clear views as to the advisability of an operation in a given case, for a patient may desire its performance simply through a magnified idea of the evil of his condition. In such instances, a plain, honest talk, with advice directed to palliation, may suffice to remove all his alarm. At other times a sexual neurasthenic may importune us to operate simply because he has been influenced by quack literature on the subject, and has detected a slight fulness of the spermatic plexus with sensitiveness of the veins, the latter, perhaps, only an item in the general hyperæsthesia of the genitals. In these cases we must decline to satisfy the whim; we must not be led away by the possible moral effect of the operation; the cold steel sound, and other appropriate measures, will accomplish more good and with more permanent effect.

We should decline to operate when there exists independently pronounced physical or mental disease, and at such time as there is intercurrent inflammation of contiguous tissues, as epididymitis, for instance.

I would advise limiting the operation to the following conditions: (1) When the varicocele is voluminous enough to cause marked deformity, interference with occupation, or skin irritation; (2) When it causes severe pain or reflex neuralgia; (3) When the testicle on the side affected is becoming atrophied; (4) When the opposite testicle is lost or seriously impaired from disease or injury; (5) When the disease is increasing, in spite of palliative measures; (6) When apparently it alone causes marked mental depression and aberration of the sexual function; (7) When a patient is desirous of entering a public service and varicocele is the only obstacle.

Operations.—To consider all the measures that have been devised and advised for the radical cure of varicocele, while historically interesting, would be useless. Their mere enumeration would entail a loss of time. Many of them have become obsolete, for various reasons, not the least important of which is the introduction and observance of aseptic and antiseptic technique. Some are dangerous, and have been discarded on that account. Hence I shall describe only three distinct methods, one subcutaneous and two open, each of which has to-day its warm partisans, and is subject to various modifications. I shall try afterward to point out their main advantages and disadvantages.

Resection of the scrotum is frequently advocated either as an operation *per se*, or as supplemental to other measures. The scrotum is so elastic that it will often stretch again if the venous tumor itself is not more or less obliterated, or will contract if the varicocele proper is remedied; consequently I deem a sacrifice of scrotal tissue usually either insufficient or superfluous, as the case may be. When operating on persons in whom the scrotum is much elongated, it suffices to bring the edges of the wound together in such manner as to change the line of incision from a horizontal to a transverse direction, as recommended by Parker.

Let it be understood, so as to save repetition, that any and all operations must be preceded by the proper preparation of the parts and the patient. The latter's bowels should be opened; he should have a warm bath; his scrotum and pubes should be shaved, then kept covered with a mild bichloride pack until the moment of operation, at which time the skin should be mopped with alcohol. Any of the operations can be satisfactorily performed under local cocaine analgesia. The two open ones may be done under general anæsthesia, if preferred for a valid reason. All must be done in every instance with the greatest care as to asepsis and antisepsis. It will be taken for granted always, that the operation is being done on the left side.

Subcutaneous Ligation.—The best of this type of operation is that devised by Keyes and bears his name. It is in reality a modification of the method practised by Ricord more than half a century ago. It is done with strong twisted sterile silk and Keyes' modification of the Reverdin straight needle, the eye of which is kept closed by a spiral spring in the handle and is opened by pressure backward on a button.

The patient should stand in a good light, leaning against the operating table. Grasping the scrotum from before backward with the left thumb and fore-finger, the vas deferens is separated from the veins and held to the inner side; it can be distinguished by its whip-cord feel. The needle, charged with a piece of silk about a foot long, is thrust through the scrotum, between the veins and the vas deferens, as high up as possible, and left there. A second needle is thrust through in a similar manner lower, near the globus major, and also left hanging. In pronounced cases, a third needle is similarly introduced between the globus minor and the veins that hang below. The patient usually feels faint by this time, if not earlier, and may be placed on his back on the table. Each ligature is now to be completed in turn in the following manner: the eye of the needle is opened by pressing back the button; the loop of silk is seized with forceps or tenaculum and the short end pulled out; the needle, with its eye closed, is pulled forward until its point gets back to the anterior puncture, but without emerging; the veins are allowed to drop back to their natural position alongside the vas; the needle is then again pushed under the dartos on the other side of the veins and brought out at the posterior puncture where the silk is still hanging; the eye of the needle is once more opened and the silk is inserted into it; the needle is finally withdrawn through the original anterior puncture and unthreaded. Two or three loops are now around the veins, and the loose ends of each are hanging in front; each set is to be seized and pulled upon to adjust it as near the veins as possible, then tied with a double knot, cut off close, and the knot made to disappear by pulling on the scrotum. A dry dressing and a support of some kind are to be applied. I use a cotton and collodion dressing at each puncture and apply a well-fitted suspensory.

The points of ligation and the testicle itself swell and become tender, the inflammation subsiding gradually after two days up to the time the patient is able to get about, in four or five days; the inflammatory exudate persists for several weeks, but is slowly absorbed.

Open Scrotal Ligation.—There are several methods of performing this operation, varying as to more or less important details. Some open the venous sheath in their dissection, others ligate without so doing; many advise resection of the veins, some do not. I shall describe the operation I prefer, which is in all essentials that originally advocated and described by Bennett.

The patient is placed on his back, the operator standing on the left. The affected veins are made tense and pressed up by grasping them with the left hand. The vas deferens at the same time is pushed back and avoided. An incision about an inch in length is made over the prominent veins, and is deepened until the thin fascia surrounding the varicocele is exposed. The vessels can now clearly be made out and need not be actually denuded. With an aneurysm needle a strong chromicized catgut ligature is slipped under the bunch of veins, as near the testicle as is deemed proper, and is tied securely, the ends being left long. The veins, in their sheath, are then freed above and drawn out of the wound to the extent that it is decided to resect. A second ligature is slipped around the freed veins as high as possible and tied in a single knot, held by an assistant. The portion between the ligatures is divided about a quarter of an inch from each ligature and removed. The upper ligature is now tightened and knotted, both ends being left long, as with the other. The wound is cleaned and dried and one thread of each ligature is passed through its corresponding stump, between the point ligated and the cut end. The stumps are then brought and held together by tying the ends of the upper ligature to those of the lower and cutting them all short. The edges of the cut are sutured with catgut or silk-worm gut, a dry dressing is applied, the scrotum is held by a snugly-fitting suspensory and the patient is put to bed.

The wound usually heals in a few days, and the stumps of the veins can be felt to be enclosed in a mass of exudate, which may take a month to disappear, although the patient may be allowed to sit up in about a week and resume any ordinary occupation in about two. He should wear a suspensory until the exudate has been absorbed.

Suprapubic Ligation.—This, which has been called also the "high" operation, has been introduced within the last two or three years and is the favorite with many army surgeons. It is done as follows:

The incision starts just above the spine of the pubic bone and is carried upward and outward, somewhat parallel with Poupart's ligament, for about an inch and a half to two inches. The superficial and the deep fascia are divided carefully, until the vessels of the cord come into view, when the latter is raised out of the wound by a little blunt dissection. The spermatic duct and artery are returned to the bottom of the wound. The veins are then dissected from the connective tissue for about two inches, ligated with catgut at each terminal point of dissection, and cut between the ligatures; the latter are left three or four inches long and are tied together so as to approximate the upper and the lower ends of the veins which are finally anchored to the external pillar of the ring. The deep and the superficial fascia are separately united with catgut suture and the skin with silk-worm gut. A dry dressing is applied and is held in place by means of a spica bandage. The wound is to be redressed in a week, when the external sutures are to be removed, and the patient is allowed to sit up in ten days.

General Observations.—It must be noted that in the description of the three types of operation I have deemed worthy of notice, great stress is laid upon the necessity of excluding the vas deferens and the spermatic artery from the ligature. Concerning the vas the reason is obvious, a practical obliteration of testicular function would otherwise followand there can be no difference of opinion. Concerning the artery the reason is the danger of sloughing or wasting of the testicle, the argument being that destruction of the organ necessarily results from a cutting off of its blood supply; yet here opinions are at variance. While the majority of writers caution against including the artery, as mentioned above, no less an authority than Bennett has said that "division of the main trunk of the artery, together with the veins, if the principles of surgical cleanliness be observed, is not only harmless to the testicle, but probably aids in ultimate relief by diminishing the pressure of blood going to the testicle." In a more recent article, this operator goes much further. He concludes that only the complete division of the whole spermatic cord, with the exception of the vas deferens and its vessels, gives certainty of a complete cure. He has done it over two hundred times, and at present resects through an incision made over the external abdominal ring. He believes that all fear of gangrene or atrophy from this procedure may be dismissed, as the vessels which accompany the vas, together with a few small ones derived from the cellular tissue, furnish sufficient nutrition to the testicle. He claims that, on the contrary, the artery, continuing "to pump a great quantity of blood into the testicle, nearly all the different vessels of which have been removed," causes an enormous engorgement which, persisting, may lead to fatty degeneration of the organ.

Notwithstanding the plausibility of the argument last outlined, it would seem safer to avoid the artery; it is not likely to produce distinctly bad effects to exclude it and it may do so to include it. I had occasion to see one case in which complete sloughing of the testicle followed section of the artery.

Each type of operation has its advocates and its detractors, which means that it possesses its advantages and disadvantages. Subcutaneous deligation has the advantage of being done quickly; is bloodless; requires no *cutting*, which is the bugaboo of so many patients; confines the patient less long; and can be considered simpler. I have frequently seen patients walk or ride home from the operating room immediately after its performance. The serious objections to it are that it is less exact as it is really done in the dark, and that it does not give the opportunity of resecting the veins, which is advisable in large varicoceles. The open scrotal operation has the advantage of being exact, also of allowing the performance of resection of the veins and the change of direction in the incision when suturing. Those who favor the other methods claim respectively that it is unnecessarily severe, and that there is more difficulty of securing perfect asepsis, owing to the locality of the wound; the patient is ordinarily laid up longer than after the subcutaneous method. The suprapubic ligation is urged by its advocates on account of the ease with which the veins can be reached at that point, and because of the greater facility in securing asepsis. Its critics argue that it causes a weakening of the walls of the abdomen at what is already a weak place, and that it demands a longer confinement in bed.

Weighing all the reasons *pro* and *con*, I favor the open scrotal operation when there is no contraindication to its performance. You can see what you are doing; you can remove what you consider undesirable and, with proper care, you can almost invariably obtain primary union. I can scarcely remember any occurrence of suppuration within the last few years, and I do remember a case in which the patient developed gonorrhœa[*] the day after the operation, yet prompt union followed. Subcutaneous ligation should be reserved for cases of comparatively small varicocele not requiring resection; for patients objecting to cutting operation; and for instances in which the minimum time of disability is paramount.

Summary.—Varicocele is a common disease, from 10 to 15 per cent. of males above puberty being affected to a noticeable extent.

In the majority of instances it causes little or no trouble.

In a certain proportion it leads to more or less pronounced symptoms, physical or psychical, direct or reflex.

Palliative measures are sufficient when the symptoms are not severe.

The only radical cure is by operation.

Open scrotal ligation and resection is the operation of choice.

Suprapubic ligation and resection may be substituted by those who prefer.

Subcutaneous ligation is proper in selected cases.

[*] Previously contracted, of course.

A Journal Entitled "Camp and Plant," published in Colorado, tells of a decidedly curious accident which occurred at Brookside in that State on April 12. A man named Martine was in his house on that date, when a rock fell from the roof of his room whereby his skull, nose, and upper jaw were fractured. He was taken to the hospital at Pueblo, but died.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By SEALE HARRIS, M.D.,
UNION SPRINGS, ALA.

PRESIDENT OF THE SOUTHEASTERN ALABAMA MEDICAL LEAGUE; PRESIDENT OF THE BULLOCK COUNTY MEDICAL SOCIETY, 1900–02; VICE-PRESIDENT OF THE TRI-STATE MEDICAL SOCIETY (GEORGIA, ALABAMA, AND TENNESSEE) 1900–01, ETC.

From the statistics of the United States census for the year 1900, bearing upon the causes of death, I find that among 1,000 deaths from all causes 109.9 were due to consumption. When these are classified according to age, it is found that among 1,000 deaths in children under fifteen years of age, 39.6 were due to consumption; among persons between the ages of fifteen and forty-five, 252.4 were from consumption; from forty-five to sixty-five, 232.5; and of those over sixty-five years of age, 260.1. Consumption thus destroys principally persons at the productive period of life; and of those dying at this time one-fourth owe their death to pulmonary tuberculosis. German statistics, which I think are more reliable, show that one-third of all deaths from fifteen years of age to forty-five are due to tuberculosis. A disease so destructive to the human race, particularly at the time of life which gives the greatest usefulness and happiness in the lives of most persons, should receive our most earnest thought and attention, and we should be prepared in every way possible to prevent the ravages of the greatest enemy to mankind.

When I say that a large proportion of cases of catarrhal pulmonary tuberculosis, in the first stage, is as certainly curable as many other diseases, I am sure that I voice the sentiment of the best authorities on tuberculosis; but after the disease has progressed to the breaking down of the pulmonary tissue and cavity formation, we all have felt the almost utter hopelessness of any but palliative treatment.

Realizing, as we must, that the health, happiness, and even lives of many of our patients and friends, as well as those intimately associated with them, depend upon our ability to make an early diagnosis of consumption, why do so many cases go on to the second and third stages before the nature of the disease is known? One reason is the utter carelessness of many people regarding matters pertaining to their health. I have seen persons with a hacking cough and progressive emaciation go for months without medical attention. I have seen others, although they and their friends suspected that they had consumption, would yet postpone for a long time consulting a physician, because they were afraid of being told that they had consumption under the impression that consumption means certain death. The laity should be taught that consumption, if treatment is begun early, is among the diseases amenable to treatment, and the earlier the diagnosis, the greater the probability of cure. A great many cases escape observation until too late because of carelessness or ignorance on the part of the physician. Many physicians, capable of making fine distinctions in diagnosis, allow their patients to go without a thorough examination, prescribing in a haphazard way, often taking the patient's diagnosis as to the nature of the trouble. The careful diagnostician, whatever may be the symptoms which he is called upon to treat, makes a thorough examination of the lungs, heart, and abdomen, and frequently finds pathological conditions which are unsuspected, and which may be the real cause of the symptoms. Then it should be remembered that several diseases may co-exist in the same

[*] Read at the first meeting of the Southeastern Alabama Medical League at Troy, Ala.

patient, the one affecting or being dependent upon the other. This is especially true of tuberculosis; it, more than any other disease, is a cause, complication, or sequel of other diseases. I have several times been surprised to find an apex diseased, when the patient had consulted me for other troubles, and having no symptoms which caused him to suspect or fear tuberculous disease.

In the several post-graduate and hospital courses I have taken in northern cities, I have been surprised to see how deficient in physical diagnosis were most of the physicians I met there, many of them graduates of colleges of great renown. I will admit that I also learned how little I knew about the subject myself. I am, therefore, willing to make the broad statement that but few, if any, medical colleges in this country, in their undergraduate courses, are as thorough as they should be in physical diagnosis. Some of them are thorough in their textbook teaching, but the students do not have the opportunity of becoming, by practical experience, proficient in physical diagnosis, or else they do not realize the importance of the subject. It is only in hospital work or in private practice that physicians become skilled in physical diagnosis.

It may not appear to the world, or to the admiring spectators, as brilliant an achievement to diagnose tuberculosis in the early stage, as to perform a laparotomy, thereby relieving conditions which, without surgical intervention, would mean almost certain death, yet the results are the same as far as the good to humanity is concerned, and it requires as much skill or learning for the physician to make such a diagnosis as for the surgeon to perform a major operation. The general practitioner certainly has the opportunity of doing more good by becoming an expert in diagnosis than he could by being proficient in surgery; yet because of the glare and glitter attending surgical operations, and because of the reputation it gives with the laity, who are deluded with the idea that it requires great nerve and skill to use the knife, many physicians dabble in surgery and fail to perfect themselves in diagnosis, particularly the physical examination of the chest.

I fear that my "subject theme may turn out a sermon" on the necessity of being thorough in general diagnosis; but right here I will confess my own sins of omission and commission in diagnosis, by failure in some cases to make a sufficiently careful examination of the patient, and in other cases by ascribing the symptoms to other causes, where later I learned they were due to incipient phthisis. However, I have resolved in the future to sin less in errors of diagnosis.

The point that I desire especially to emphasize is that if we will examine all of our patients thoroughly we will find more cases of tuberculosis in the curable stage. If we examine ninety and nine normal chests and find the hundredth with a diseased apex, we not only become more proficient in diagnosis, but are repaid a hundred fold for our trouble.

There are certain conditions which should in every case demand a thorough examination of the lungs, no matter what may be the other symptoms. The principal ones of those which occur to me now are:

Gradual loss of weight and strength without obvious cause. This may be for a time the only symptom. Slight dyspnœa after exertion is often seen early. An evening rise of temperature of 100° to 101° F., and in some instances a subnormal morning temperature, indicate tubercle formation.

A frequent pulse, from 85 to 110, without apparent cause, should excite suspicion.

I cannot lay too much stress upon indigestion as being not only a frequent predisposing factor in the production of tuberculosis, but one of the earliest symptoms in many cases. Anorexia and morning nausea are not infrequently seen, and they are symptoms which materially affect the prognosis, because if a tuberculous patient cannot be well nourished his chances for recovery are greatly lessened.

Chest pains, particularly in the upper part of the chest, may be due to a slight fibrinous pleurisy, or to myalgia from coughing. If these pains are unilateral and constantly recur, they are sometimes significant of phthisis.

Fistulo in ano sometimes calls our attention to the tuberculous diathesis, and an examination of the lungs may show a diseased apex.

If to any one or more of these symptoms there is added a slight dry and hacking cough, which is more annoying at night or early in the morning, whether there is absence of expectoration or the sputum is scanty and mucoid in character, tuberculosis may be strongly suspected, even if there are no physical signs to prove it.

Sometimes tuberculosis follows or is coincident with a chronic bronchitis, or a bronchopneumonia may be of tuberculous origin. In such cases, the sputum should be repeatedly examined for the tubercle bacillus. The presence of the bacillus, however, is only confirmatory, and its absence is certainly no evidence that the process is not tuberculous.

Indeed, in many cases a tuberculous infiltration or deposit at the apex can be diagnosed before any sputum is thrown off or there is any breaking down of lung tissue with liberation of bacteria. I use the microscope constantly as an aid to diagnosis, and in many cases, even in the earliest stages, the bacilli may be found in the sputum, but the absence of the specific germ is only negative evidence.

I have under my care now a case of catarrhal tuberculosis of the left apex, with all the physical signs of the first stage. I have watched the case for two months, and while the woman has a slight hacking cough, there has never been the slightest expectoration. I obtained by means of a laryngeal application a specimen of the secretion from the larynx just after an attack of coughing, but microscopic examination showed no tubercle bacilli; yet I am as positive of the diagnosis of consumption as if there were signs of cavity formation with the sputum teeming with the specific germs.

In making a diagnosis of tuberculosis the influence of heredity should be considered, as should also a history of constant exposure to the infection, as of a person living in the house with a tuberculous subject. The tuberculin test or reaction is recommended by Musser and others as a means of early diagnosis, but is condemned by other equally eminent authorities. Personally I have had no experience with it.

Below I give the physical signs of the most common form of pulmonary tuberculosis, *i. e.* the catarrhal or bronchopneumonic type, before there has been softening of the diseased lung tissue with subsequent cavity formation:

Inspection, in the stage of beginning deposit, is often negative, though there may be a slight flattening of one infraclavicular space, or an undue prominence of one clavicle, with slight impairment of motion of the affected lung. At a later period, when consolidation has taken place, there is a decided depression of surface of the infraclavicular region and markedly less motion on the same side. There is a loss of flesh, with often the dusky pallor of anæmia, or an intermitting hectic flush. Some authors call attention to the enlargement or prominence of the superficial veins over the affected area. I have never seen this condition except in cases of long standing; and as it is probably a collateral circulation due to prolonged obstructive disease of the lung, it seems to me that probably in all cases it would be of late appearance. In some cases limitation of the excursion of the diaphragm (Litten's sign) may be one of the earliest signs of tuberculosis.

The *x*-ray in expert hands is said to give a light shadow over the disease area, but it occurs to me that there would have to be considerable consolidation before the *x*-ray could be of value.

Palpation, in the early stage, may or may not give increased vocal fremitus, but where there is consolidation the fremitus is marked. *Mensuration* generally shows diminished expansion, on one or both sides.

Percussion gives a slightly higher pitch, or impaired resonance, above, on, or below, the clavicle. This is sometimes better brought out if the patient's mouth is kept open (Wintrich's change of note), or if he is instructed to hold his breath at the end of expiration. When consolidation is complete there is positive dulness over the affected area. It should be remembered that normally, particularly in right-handed persons, percussion over the right lung gives a higher pitched, or slightly duller, note than on the left side.

On *auscultation*, in the very early stage, the respiratory murmur may simply be rougher or harsher than normal, or it may be feeble or diminished. The breathing may be of the jerky, so-called cog-wheel variety, but this is often seen in nervous patients with normal lungs, and should not be considered, except with other signs. Flint's bronchovesicular murmur, or as Page better terms it, vesiculobronchial respiration, is the one pathognomonic sign of incipient pulmonary tuberculosis. It consists of a roughened, loud inspiratory vesicular murmur, with a relatively prolonged, blowing (bronchial), expiratory sound. It should not be forgotten that, normally, in the right infraclavicular region, because of the proximity to the surface of the large right bronchus, there is heard a type of bronchovesicular breathing. Crepitant and crackling râles or clicking sounds at the end of inspiration are sometimes heard at the apex, and are always due to tuberculous infiltration. They are best brought out by a full inspiration or by coughing. As the consolidation increases the vesicular character of the breathing is gradually lost, and is replaced by pure bronchial breathing. Frequently with these sounds are heard the râles of a concurrent acute or chronic bronchitis, and sometimes the friction sound of a fibrinous pleurisy.

Da Costa has called attention to a murmur or blowing sound over the subclavian or pulmonary artery, when there is a tuberculous deposit in the left apex. I have noted it several times, and regard it of some value. It is probably due to a slight pressure of a tuberculous deposit upon those arteries.

While the great majority of cases of phthisis begin in the apex, occasionally the base of the lung is first involved. This, however, generally succeeds a lobar pneumonia or a pleurisy, which provides the *locus minoris resistentiæ* for the tubercle bacilli. In such cases the physical signs will be found over the affected area of lung.

In the acute catarrhal type, which is also known as *phthisis florida*, or galloping consumption, the course is very rapid, many cases proving fatal in a very short time. We see this type frequently among the Southern negroes. In such cases the physical signs of the stages of infiltration and consolidation pass very rapidly into that of cavity formation. The fibroid type, which is very chronic in its course, generally succeeds, or is associated with a pleurisy, and presents somewhat the same physical signs as a pleurisy with retraction of the chest wall.

Acute miliary tuberculosis may not present any distinctive physical signs, indeed in many cases a hyperresonant note is heard upon percussion. The diagnosis is made from the high and fluctuating fevers and personal or family history of tuberculosis, and in some cases from the presence of the tubercle bacilli in the sputum.

The recognition of incipient pulmonary tuberculosis is one of the most important diagnoses which the physician is ever called upon to make, but when made early the reward is so great that the subject should merit our most earnest consideration.

SOME REFLECTIONS ON CASES OF ACUTE INTESTINAL OBSTRUCTION.

By H. BEECKMAN DELATOUR, M.D.,
BROOKLYN, N. Y.
SURGEON TO LONG ISLAND COLLEGE HOSPITAL, ST. JOHN'S HOSPITAL, AND NORWEGIAN HOSPITAL.

Acute intestinal obstruction is a symptom of a number of different lesions, and in considering its treatment we must understand from the first that this means the treatment of very different mechanical conditions. Acute obstruction may be due to the presence of tumors which have been some time in existence, or may be due to conditions of immediate development. The various cases of obstruction may be classed under the following heads: (1) Internal hernias; (2) Angulation due to bands or faulty attachments; (3) Volvulus and intussusception; (4) Tumors in the walls of the intestines; (5) Foreign bodies within the lumen of bowel.

The exact method of treatment must vary according to the condition present, so that a more or less accurate diagnosis should be made before operation is begun. It is true that nearly all these cases, for a positive diagnosis, require an exploratory operation; yet it is equally true that some cases are more easily operated through a lateral than a median incision. In arriving at the decision as to the point of operation, we have then to carefully consider the history of the case.

A few cases will serve to illustrate the various classes:

First—A young woman, twenty-one years old, was admitted to the St. John's Hospital with the following history: She was suddenly seized with abdominal pain, referred to the umbilicus; there was an inability to move the bowels; early onset of vomiting; very moderate distention of the abdomen; rapid pulse and severe prostration. A diagnosis of obstruction high up in the small intestine was made, and due probably to either a band or internal hernia. The point of obstruction was so located because of the early appearance of vomiting and moderate distention. A median incision was determined on, and the abdomen opened in the median line at the level of the umbilicus. The hand was introduced, and a coil of small intestine found strangulated in the fossa duodeno-jejunalis. This was liberated, the abdominal incision closed, and a perfect recovery resulted. Three such cases have come under my personal observation.

In the second class, those cases due to angulation, bands, etc., we have a very interesting class to deal with. In some cases the obstruction seems to be due not to any actual mechanical obstruction, but to an angulation brought about by the sudden filling of a portion of the bowel with gas. A section of the bowel suddenly becomes filled with gas, and so presses on a distal coil that it completely shuts it off, and the greater the pressure becomes, the more complete the obstruction. In these cases the rational treatment would be to place the bowel at rest and try to favor the absorption or more general distribution of the gas. Unfortunately, this is seldom done. Most strenuous efforts are made to get a movement, and injections are given, and cathartics of increasing strength are administered. The use of enemata is certainly not nearly as objectionable as the attempts to open the bowels by means of cathartics, for these simply set up a peristalsis, which soon reverses itself and brings on vomiting. This, of course, weakens the patient and tends to prevent successful operative interference.

One of the points I desire to make in this paper is not to resort to strong cathartics to overcome symptoms of obstruction; whatever you do, do from below. Two cases of this character I will give in detail.

Mrs. B., fifty-two years old, was admitted to Dr. Fowler's service at the Methodist Episcopal Hospital, with symptoms of acute obstruction of several days' standing. Her condition was such that it was considered best to give her relief by an artificial anus. This was done, and, twenty-four hours after the opening, a normal evacuation of the bowels took place. At the end of two weeks, the artificial anus was closed and the patient discharged. Two years later she came into my service at the Norwegian Hospital, with a large strangulated hernia at the site of the former operation. The patient has never worn any means of support even after she discovered the hernia developing. There had been no movement of the bowels for a week, the abdomen was much distended, and fecal vomiting had existed for several hours. The hernial sac was opened and found to contain a coil of small intestine, held down and constricted by a band within the sac. This band was severed, and the distended bowel was punctured so as to reduce the distention, the point of puncture being closed by Lembert suture. The patient suffered much shock, and never completely rallied. She died on the fifth day. In this case no tumor existed in the intestine, and it is fair to presume that the original attack was due to angulation.

A second case, Mrs. H., sixty-two years old, gave the following history: She had always suffered with indigestion and the development of much gas. Two weeks before admission she was seized with a severe abdominal pain and distention, and inability to move the bowels. All cathartics administered were immediately followed by vomiting. This was allowed to go on for over two weeks. When I saw her she was much emaciated, abdomen greatly distended, and vomiting frequent. Under local anæsthesia, an artificial anus was made at the cæcum. On opening the bowel there was a continuous profuse discharge for twelve hours. At the end of this time the abdomen was nearly flat, and a natural movement occurred. From that time on the bowels continued to move naturally, only a small amount coming from the artificial anus at a time. She refused further operation. A year later I was called to see her, and found an intussusception of the ileum through the ileocæcal valve and artificial anus, the intussusceptum being outside of the body. This had occurred before, and had been replaced, but on this occasion it was allowed to remain out so long that it became so œdematous that reduction was impossible through the ring in the abdominal muscles. Under anæsthesia the abdomen was opened at the site of the former operation, and when the constriction was relieved the reduction of the intussusception was quite easy. The edges of the intestine were then separated from the parietal peritoneum, and the opening in the cæcum closed, as a careful and thorough examination of the entire intestinal tract failed to show any tumor or point of obstruction. The patient made an excellent recovery from this operation, but, curiously, six months later, died from an attack of acute dysentery.

Another interesting case was one due to a band of omentum. The patient, a girl of twenty years, was admitted to St. John's Hospital with a history of severe abdominal pains, followed by persistent vomiting. The patient came in from the country sitting in an ordinary car of the Long Island Railroad. She was so sick that no history could be taken from her, and her physician was not with her. She was stimulated, and allowed to recover from the shock of transportation as far as possible. A median abdominal incision was then made, and the omentum found adherent to the fundus of the uterus, and a coil of small intestine, about eight inches, caught behind this, was completely gangrenous. This was resected after the band had been divided, and the ends united by means of the Murphy button. The patient never rallied, and died twelve hours later. At the time of the operation it was suggested that the uterus had probably been punctured, and that the tip of the omentum became adherent to this point. Investigation proved this to be true. This case would naturally lead one to reason that after pelvic operations, where exposed surfaces for adhesions exist, one should be especially careful not to allow the omentum to dip down into the pelvis.

In a case of my own, a year after an hysterectomy, the patient was brought back to the hospital suffering with acute obstruction, which at operation was found to be due to a similar band of omentum adherent in the pelvis.

Tumors are frequently the cause of acute obstruction. It seems very difficult for the general practitioner to realize that acute obstruction may appear in cases where the lesion is a tumor of slow development. That is seen so frequently that I believe we should emphasize it. If the history is carefully gone into, as a rule we can get a history, extending back some six months to a year, of intestinal disturbances with difficulty to move the bowels, but the symptoms are so slight and commonplace that little attention is paid to them. Suddenly the patient is unable to get a movement of the bowels; he takes some cathartic, tries enemata of several kinds, and all without effect. Then he calls in the family physician, who goes through the entire list of physics and enemata with no result, unless it be an increase of the distress and possibly the induction of vomiting. Quite a number of such cases have come under our care, and they have been dealt with differently, according to the conditions found at operation.

Three plans have been followed—first the relief of the condition by the forming of an artificial anus, to be followed later by an anastomosis or a resection of the growth with anastomosis; second, the immediate resection of the growth with anastomosis; and third, the production of a permanent artificial anus.

Mrs. M., thirty-eight years of age, was referred to me by Dr. Ives. She had suffered for a year or more with floating kidney of the right side, had more or less difficulty in moving the bowels, had been confined within a few months. During the night she was suddenly seized with general abdominal pain, which was very acute and was accompanied by vomiting and complete obstruction of the bowels. The next morning the pain had subsided some, but there was marked tenderness on the right side, some temperature and increase of pulse rate. It was a question whether the tenderness was due to an appendicitis or to the old kidney condition. The pains were paroxysmal; vomiting was nearly constant. I saw her in consultation the next afternoon, and at that time the signs and symptoms were about the same, with marked distention added. The case was not a clear case of appendicitis, nor could we find any changes in the urine to lead us to believe it was a pus kidney. She was at once removed to St. John's Hospital and operated upon that evening. A right lateral section was made rather higher than usual. Exploration revealed the appendix much distended with gas, elongated and congested, yet it was evident that it was not the primary cause of the trouble. The appendix was removed. The kidney was examined and found normal, examination of the hepatic flexure of the colon revealed nothing; but at the splenic flexure a distinct mass could be felt occupying the entire bowel. It was decided to make an artificial anus, and, at a later date, attack the growth; accordingly, the cæcum was brought into the wound, sutured, and then opened. The patient made a prompt recovery and, two weeks later, was again subjected to operation. Knowing the location of the growth, an incision was made on the left side, beginning at the free border of the ribs and carried downward along the outer edge of the rectus for four inches. This exposed the growth, which was resected, about four inches of the transverse colon being removed, and an end-to-end anastomosis by suture was made. The patient reacted well, and three weeks later was discharged from the hospital. Nearly two years have now elapsed without any sign of recurrence.

Belonging to the same class was the case of Mr. K., fifty-four years of age, also a patient of Dr. Ives. He was suddenly seized with pain in the hypochondriac region and complete obstruction of the bowels. He gave a history of the abdominal distress extending over several months, with a feeling of the gas in the bowel passing to a certain point and giving pain, but once past this point the pain ceased. Considerable flesh had been lost. For twelve hours efforts to move the bowels by enemata were employed, but without result. The diagnosis of obstruction due to a new growth was made, and operation advised. He was removed to St. John's hospital, and a right lateral incision was made for the purpose of producing an artificial anus, using the cæcum. Exploration revealed a mass in the transverse colon. The cæcum was brought into the abdominal wound and the bowel immediately opened. Patient was immediately relieved, and during the next three weeks gained considerable strength. During the second week there were normal movements of the bowel for three days. This was evidently the result of leakage through the growth and accummulation in the descending colon, for, after an enema had been given, no further movements resulted.

Three weeks after the first operation, a second one was performed. This time a median incision was made just below the umbilicus. The hand was introduced and the growth located at the splenic flexure, but in such a position that removal was impossible. The ileum was then sought and brought over to the sigmoid flexure, where an anastomosis was made by means of a Murphy button. The button came away on the twentieth day. The patient had one or two normal movements each day, and no longer had the sensation of gas being arrested at a certain point, and then, failing to get by, producing pain. This sensation continued even while the artificial anus was open before the anastomosis was made.

At the same time the artificial anus was closed in the following simple manner: An incision was carried around the margin where skin and mucous membrane met and the dissection carried through the abdominal wall. A purse-string suture was then passed around the base of the funnel-shaped process, and after invagination of this process, the suture was tightened. This closed the opening in the intestine, and the superficial wound was allowed to granulate. This method of closing could be easily accomplished under cocaine anæsthesia. This patient died eight months later, apparently from an internal hemorrhage.

When the growth is low down in the descending colon, or sigmoid efforts at excision are not as successful as when the obstruction is high up, for it is is much more difficult to accomplish an anastomosis between the small intestine and the rectum˙ and owing to the anatomical relations of the descending colon, resection is much more difficult. In two cases operated upon by myself it seemed almost impossible to prevent leakage of fecal matter during the manipulations. Both cases died of peritonitis on the fourth and fifth days, respectively.

Conclusions.—The sudden onset of obstruction of the bowels does not always mean the presence of a recent lesion, especially in those at or beyond forty years of age.

In many cases the symptoms may point to an attack of appendicitis, as the appendix becomes distended by gas or fecal matter.

It is best in all cases where a new growth is suspected, or where there is much distension, to first make an artificial anus, and to use the cæcum for this. At this time do not spend valuable time, and produce some shock, by making a thorough exploration of the entire abdomen, in order to satisfy yourself of the exact condition.

Always open the intestine immediately, as you need to give relief as soon as possible, and there is no danger of leakage of fæces back into the abdomen, provided the exit at the anus is not blocked by too tight dressings. Better leave the wound exposed, the nurse being instructed to clean away the fecal matter as it appears.

Do not be contented to leave these cases with the artificial opening, unless at the primary operation the tumor has been found immovable and anastomosis impossible, for many cases may live months with the tumor *in situ* if the current of fecal matter is diverted by placing the loop of intestine containing it out of the fecal current.

73 Eighth Avenue, Borough of Brooklyn.

A New Medical Superintendent at Molokai.

Dr. W. J. Goodhue, superintendent of Emerson Hospital, Kauai, has been appointed medical superintendent of the Molokai Leper Settlement. Dr. Goodhue is thirty-two years old and a graduate of Rush Medical College, Chicago, 1897. He was the unanimous choice of the Hawaiian Board of Health over some forty-five other applicants for the position, and goes to Molokai for special scientific work for the government. The value of photography and *x*-ray treatment will be thoroughly investigated, as well as other curative measures. It is the intention of the new superintendent also to investigate the causes of leprosy and, in connection with this, if possible, discover what part the mosquito plays in the propagation of the disease.—*Southern California Practitioner.*

DULNESS IN APPENDICITIS.

By H. T. MILLER, M.D.,
SPRINGFIELD, O.
SURGEON TO THE CITY HOSPITAL.

In the symptom "dulness" I believe that we have an infallible means of differentiating in appendicitis between cases that are operative and non-operative. In four years' observation of forty-one cases this symptom has never failed me; and my experience since I contributed an article to the Medical Record, in February, 1901, on "The Clinical Significance of Dulness in Appendicitis" has only tended to clinch my faith in this symptom. In but one instance did this symptom seemingly fail me, and in this particular instance the dulness had disappeared before the operation. It was in a child five years old. The symptoms were those of an attack of fulminating appendicitis, and on account of the seemingly severe pain a careful examination was impossible. Under anæsthesia the dulness entirely disappeared, and upon opening the abdomen the appendix was found to be in a normal condition.

Every rule has its exception, yet I firmly believe that should we adhere to this symptom of dulness we shall be less likely to err in determining the course to pursue in the treatment of appendicitis. There is one element in the treatment of all diseases which I do not believe any one will ignore, and that is the intuitive knowledge which goes to make the successful diagnostician. Physicians are born and not made. It is this instinctive knowledge which prompts a great many successful practitioners to pursue the proper course. To those who are not endowed with this gift the practice of medicine is strewn with many pitfalls, and, though every day adds to our scientific knowledge of diseases and their treatment, there are men of acknowledged experience who at times lack the power of differentiation and selection. What is a serious case to one is a comparatively simple one to another. And so with the treatment. One says all cases are surgical, another that he never loses a case save by surgical interference. It is a mistake to conclude that every pain in the right iliac region is appendicitis as it is to say that every pain in the side that is relieved is a case of appendicitis cured. It is on record that tonsillitis and pneumonia have been mistaken for appendicitis.

There are not a few of the profession who still believe that appendicitis can be cured without surgical intervention, and who claim that they have never lost a case. Either they have never treated a case of fulminating appendicitis or else the surgeon was called in at the eleventh hour and the patient died under the knife. It is also a mistake to say that every case operated upon is saved. It is a fact that cases of supposed appendicitis have been operated upon in which a normal appendix was found and the patient died. As well might we say that there is no need of a ship ever sinking. When pus is present it is just as necessary to use the knife as it is to resort to food to sustain life. Pus as pus is never absorbed then its presence is a veritable sword of Damocles ready to destroy the victim at any moment. From my own experience I can say, without reservation, that never was a case of appendicitis, in which there was pus formation, cured save by an operation. In only one single instance did I ever know of a case of appendicitis in which the presence of pus was diagnosed, recover without operative intervention, and in this instance the abscess broke into and escaped through the bowels.

When to operate is still an undecided question. We are not all agreed that every case is operable, nor do we believe that all cases can be saved without surgical intervention. I believe that when we have a case of appendicitis without the formation of an inflammatory exudate we can afford to wait, but with the occurrence of dulness it is jeopardizing the life of the patient to defer operative interference. In an acute attack of appendicitis with dulness, persisting from twenty-four to forty-eight hours, and after the bowels have been moved, one should operate, and the chances are that pus will be found. In a recurrent attack of appendicitis with dulness, even if the temperature and pulse are normal and the patient is able to be up and around, one should operate, and one will most likely find an indurated appendix with adhesions around the appendix and cæcum.

In the former case an immediate operation is the only recourse, in the latter the surgeon will by operating anticipate an outbreak with pus formation. In acute attacks of appendicitis without dulness the case should be treated conservatively; should dulness make its appearance and remain, the medical attendant will make no mistake, in my opinion, in advising surgical intervention the probabilities are that if pus is not already formed the operator will find an injected appendix with a plastic exudation and threatening formation.

In forty-one cases coming under my observation dulness was found in twenty-four. In the twenty-four pus was diagnosed by the symptom of dulness in seventeen; verified in fourteen by operation, in two by post-mortem examination, and in one by pus escaping through the bowels, all symptoms of appendicitis at once abating. In one case, second attack, in which dulness covered an area about the size of a hand, and gradually diminished to an area about the size of a silver dollar, all acute symptoms having subsided, an indurated appendix, with possible adhesions, was diagnosed and found. In two cases operated on, in which pain but no dulness was present, an adherent appendix was found. In one, in which dulness was present but disappearing under anæsthesia, a normal appendix was found. In one case with marked dulness, little pain, febrile symptoms, tumor irregular in outline and movable, operation revealed tuberculosis of the cæcum and appendix. In one case with pronounced dulness, no febrile symptoms, tumor regular in outline and freely movable, operation revealed a floating kidney. In one case with no dulness, but intense pain upon pressure, operation revealed adhesions between the ovary and appendix. The remaining seventeen cases had all the classical symptoms of appendicitis, without the dulness, and all have seemingly recovered. In two of these cases there have been as many as three attacks, and it is now over two years and neither has had a recurrence, nor experienced any inconvenience.

Every pus case that I have had was either saved by operation or died from the need of one; or the operation was done too late. In two cases operation was deferred until after septic peritonitis had resulted, death following.

I do not wish the reader to conclude that I believe that in every case of appendicitis with dulness we find pus, but I do believe that in every case with dulness the conditions are such that no mistake is made by surgical interference. Pain in the region of the appendix does not always mean appendicitis, but localized dulness with the associated symptoms of appendicitis always does.

Tuberculosis of the appendix and cæcum is usually a subacute or chronic process. The tumor found in the tuberculous mass has irregular edges, and is, as a rule, freely movable. The pain is dull, while in appendicitis it is acute. Afebrile symptoms differ. When pus forms in the tuberculous mass it is then a difficult matter to differentiate between this condition and an acute attack of appendicitis. The history of the case may assist one in arriving at a correct diagnosis.

In floating kidney the tumor is smooth and has the outlines of a kidney, is freely movable, and at times entirely disappearing. Pain is of a dragging nature and is generally relieved by rest. Febrile symptoms are absent.

Between gallstones complicated with empyema of the gall-bladder it is often a very difficult matter to differentiate, or when the appendix is reflected toward the gall-bladder. Frequently the two conditions co-exist. To operate for appendicitis and find gallstones may happen to any surgeon. In one case in operation for gallstones I encountered the appendix touching the lower border of the bladder and a floating kidney immediately behind it. Pain is referred to the right hypochondrium. Dulness extends to the liver.

In fecal impaction, pain is not marked, but is dull and obscure when present. The tumor presents itself as a doughy swelling. No fever.

In carcinoma the symptoms come on slowly. The tumor is hard and irregular, and movable through a limited space.

In intestinal obstruction, nausea and vomiting is a constant symptom; the matter vomited is first bilious and finally fecal. The temperature generally subnormal.

In pyosalpinx we find pain and a tumor below McBurney's point. The appendix may, however, be involved.

THE DOCTOR AND THE SCHOOL TEACHER, CAN THEY NOT WORK MORE IN HARMONY?

By RICHARD COLE NEWTON, M.D.,
MONTCLAIR, N. J.

NOTHING can show more plainly the need of a well-educated, thoughtful, and conservative medical profession than the present status of the question of the education of children. There is no problem of greater importance before the country to-day than this one. And while here and there a physician has distinguished himself by contributing toward its elucidation, the profession in general has been, and still is, backward in making itself felt in this direction.

Apparently nine out of ten family doctors are content to wait until a child actually breaks down in school, and perhaps becomes an epileptic or a consumptive, a neurasthenic or a hypochondriac, or develops some other diseased condition, before interfering. That the foregoing is not an exaggerated statement seems, alas! but too true. Another unfortunate complication of the question lies in the fact that there seems to be a growing antipathy between teachers and doctors. The former are unquestionably too much imbued with the determination to get as much work out of the scholars as possible, while the latter are, frequently, at least, too inconsiderate in ordering all school work stopped and taking the scholars entirely away from their teachers, when oftentimes a partial intermission of the studies, or a variation of them, might be better for the child than complete suspension of mental exercise. In many cases, at least, sloth of the mind is as injurious to the growing child as bodily inactivity, or over-indulgence of the appetites.

To control and direct the growing intellect of a delicate child is a matter of the greatest nicety. In short, so interwoven and inseparable are physical and psychical development, that one cannot be improperly developed without injury to the other. Their growth and expansion must be synchronous and concatenated, or disaster may result.

If these statements are true, and I believe that no thoughtful person will deny their truth, the corollary is obvious that the education of the growing child should be both physical and mental; that his moral, mental, and physical hygiene must be equally considered; and it is just here that the medical profession has failed in its duty.

Teachers have seen the logic of this position, and have steadily improved their courses of instruction by adding physical culture, in various modifications, to their curricula. Yet the nervous and anæmic girls and dyspeptic and hollow-chested boys in every school attest the sad fact that these efforts have been only partly successful. Cases appear constantly in which the scholar has worked far beyond his strength, and that right under the eyes of a careful and conscientious teacher. The reason of this is not far to seek. The teacher is not a clinician, and the signs of impending breakdown in the child have not been observed or have been ignored or misinterpreted. Consequently, the medical profession must fill this gap. Medical men must supervise all forms of instruction and must determine, not alone the best general rules for both mental and physical education, but must watch the individual child and study his or her peculiarities and limitations. Only a skilled clinician can do this, therefore, just here the physician is indispensable, because it is here that the teacher has failed. On the other hand, our profession has not risen to the situation because its members are, as a class, not sufficiently well versed in modern educational methods. The teachers understand their part of the work better than we do ours. They are successful in getting work out of the children, while we, generally speaking, are only able to interfere and stop the course of a child's education after he has done himself an injury, instead of which we should have been able to so direct and modify his studies and course of life that he might have received the education that he needed without injury to his health. In other words, teachers and physicians should work hand in hand. We should be aiding and abetting, instead of antagonizing each other. Both are actuated by a common desire for the child's greatest good, and that there should be any antagonism is not only needless, it is detrimental to the cause in which both are enlisted. Therefore, the profession must shake off its lethargy and take a more active interest in this most important question. It does not speak well for our capacity, nor for our devotion to the interests of our patients, that we should allow any of them to do themselves injury and then try, in our often ineffectual way, to repair the evil, instead of having interfered beforehand to prevent it.

I cannot but feel that it is because our profession has been too lax that these constantly recurring evils of overstudy and overwork, as well as the equally great evils of bad school hygiene and improper methods of life, have become so potent to the injury of children. Again, until our profession shall consist of better-educated men, and men who shall have made a thorough study of educational methods, our opinions on this topic will not receive proper respect from educators or the public. So long as our attitude shall seem to be only one of opposition, without a full understanding of the entire question, our influence in this direction cannot be as powerful as it ought to be. Furthermore, the problems of the education of children will, I believe never be satisfactorily solved until physicians shall have had more to say upon the subject.

The crying need for better physical education for adults and young people who have left school is being more or less fully met by a number of instructors, or teachers, who advertise freely that by ten to twenty minutes' exercise daily, according to the methods they teach, one can become healthy, strong, erect, deep-chested, free from insomnia, nervousness, headache, constipation, torpidity of the liver, obesity, anæmia, etc.

And that they measurably, at least, succeed in their efforts "abundant unsolicited testimonials" seem to bear witness. No doubt any practising physician can cite a number of cases where the exercises taught by these persons, or similar exercises, have been of the greatest benefit. Yet, can any one claim that physicians as a class have taken the pains necessary to inform themselves of what these exercises are, how they are to be performed, and what they may be expected to accomplish? If a tithe of the claims of the so-called "physical culturists" are true, our profession is showing itself very lax if it does not investigate the matter fully, and make itself able to pass an opinion upon every aspect of this form of education. One of these teachers writes that he "makes no tirade against medicine," although "physical culturists have been especially guilty of blackguarding physicians." This shows at least that with this class of teachers, also, the profession has not established that *entente cordiale* which should subsist as well with these as with the school teachers.

In fact while there may perhaps be some diversity of opinion as to how well a doctor should be qualified to pass judgment upon a question of ordinary school work, theoretically, at least there can be no doubt that upon every aspect of physical culture his opinion should be paramount and his judgment indisputable. Can we assert that the profession has fitted itself to pass authoritatively upon these questions? Are doctors thoroughly qualified to discuss the claims of the writer that I have just quoted, who asserts that pulmonary gymnastics are the *sine qua non* for physical well-being? He writes that he has a list of over two hundred athletes who have died from consumption and claims that this was not due to dissipation or assuming undue risks, but to an improper development of the lungs; or, rather, to the fact that these athletes have not taken the proper steps to develop their lungs. Now if this is true at all, it is a statement of the greatest importance. Are we capable of discussing it intelligently with its author? He asserts that he has measured 20,000 persons and finds that, as regards at least half of these, their average breathing capacity is from 225 to 275 cubic inches, whereas the normal should be between 300 and 400 cubic inches, etc. What physician or writer on diseases of the thorax can point to such an extended experience? Our author asserts boldly that "not one person in a hundred has strong lungs and breathes fully."

He claims, also, that the 300,000 persons who, according to the census of 1900, die annually of phthisis and pneumonia in the United States, could have been saved, or at least greatly benefited and that if they had developed their lungs according to his method they would not have contracted these diseases. These are weighty claims but it does not answer them to say pooh! pooh! The writer just quoted is not the only one who claims that "deep breathing," or similar pulmonary exercise, has enormous power for good, and that it has been greatly neglected in most forms of exercise. If the profession is thoroughly competent to discuss these questions, why do we hear so little from physicians in regard to them? It would almost seem that, like the Pharisees of old we are paying tithe of mint and anise and cumin, and omitting the weightier matters of the law.

These important questions should not be left to empirics nor to lay teachers no matter how painstaking and conscientious.

There is no doubt that physical culture will become more and more a part of the education of every child, and will be more and more used in the treatment of various diseased or feeble conditions in adults. Physical development for men and women is in the air. It is even becoming fashionable. Its growth has been constant and rapid, almost marvelous, during the past few years; and it will continue to grow. We must at least fully inform ourselves in regard to it, and be able to give a reason for the faith that is in us.

Let us study this whole matter thoroughly and carefully. The claims of these teachers, whose honesty and devotion we do not question, must be thoroughly sifted. The risks and evils, if any, attending their various methods of instruction must be noted, and made public. The physician of the future must be able to direct both the physical and mental education and development of both adults and children; otherwise, he will fail of one of his greatest and noblest duties, and he will lose, in the estimation of the public much of the prestige and honor now accorded him.

FOREIGN BODIES ACCIDENTALLY LEFT WITHIN THE ABDOMINAL CAVITY; HOW TO PREVENT THE OCCURRENCE.

By HOWARD LILIENTHAL M.D.,
NEW YORK
ATTENDING SURGEON TO MT. SINAI HOSPITAL.

THERE is but one absolutely certain way to prevent the accidental leaving of foreign bodies within the abdominal cavity during the performance of surgical operations, and that is to avoid placing any packing or other object entirely within the cavity. I have never found it necessary to insert a whole packing or sponge within the abdomen. No enumeration before and after the operation can be so free from possible error that the accident may not occur. If, however, the gauze is cut in lengths sufficient to permit at least two-thirds of each piece to remain outside of the wound and if no more than one-third of each strip is used as a packing, it is obvious that none can be lost. This has been thoroughly tested by me for more than four years and the fact practically proved. The method is a simple one almost too simple to attract the attention it deserves; yet, when one considers that many human lives have been sacrificed as the result of such mishaps, and that many a carefully planned and well-executed piece of work has been rendered useless through a perfectly preventable cause the full importance of the subject will be realized.

[illegible] MADISON AVENUE

Treatment of Persistent Hiccough.—Dr. William McDonald of Providence, R. I., writes in the *Albany Medical Annals* for September on persistent hiccough and its treatment. He says "if there is anything humorous in the consideration of the subject it is to be found in glancing over the list of remedies which are supposed to have special efficacy. The list is headed by one which is nothing if not a delicate drug, *i. e.* the web of the black spider. Many others are noted, such as musk, camphor, ammonia, wine and spirits, ether and chloroform, by mouth, by inhalation, and as an abdominal spray; strychnine, prussic acid, alkalies, bromides, atropine, opium, valerian, asafœtida, castor oil, quinine, arsenic, turpentine, anise, mint, cloves, Hoffman's anodyne, nitroglycerin, inhalation of Scotch snuff, pilocarpine, cannabis indica, chloral, sulfonal, inhalation of burning paper and of capsicum, salicylates, bleeding, cupping, vomiting, purging, poultice of garlic and hemlock, warm plasters, anodyne frictions, ice applied at various points, galvanism along phrenic nerve, at back of neck and over the epigastrium, static electricity, lavage, depression and regular traction of tongue, pressure upon phrenic nerve, large enemata, suggestion, distraction of attention, fright, etc. Dr. McDonald is of opinion that in certain cases the drug given probably did effect a cure, and of this number some were inadvertent cures, others the result of deliberate aim at the conditions producing the spasm. In a large number of cases, however, the effect ascribed to the drug was neither logical nor accidental. There was simply no relation between the action of the drug and the cure. The troublesome symptom was either self-limited or ceased because of some agency whose action was not taken into account. . . . In all cases we should give rational treatment directed at the cause. If this cannot be discovered then we can use measures which would have an improving effect upon the whole economy. Such would be thorough rest, both mental and physical, massage, hydrotherapy, electricity, care of the diet, and, in a word, general hygienic methods. Failing in this last, one, if he chose, could begin at the top of the list of empirical remedies, traveling down until either his own patience or that of the victim became exhausted. The moral—concludes Dr. McDonald—to be found in the history of hiccough is self-evident. Treat, not the name of the disease, not even the disease, but the patient. Perhaps in all medicine we could find scarcely a disease, condition, or a symptom in which we could trace so easily the faltering, zig-zag footprints of a groping empiricism.

Some Points in Practical Surgery Suggested by the Study of the Life and Work of John Hunter.—Mr. Reginald Harrison, F.R.C.S., took this as the subject of the Hunterian Lecture delivered by him in London on February 26. Rereferring to Hunter's teaching, that to cure urinary fistulæ it is necessary to provide for the urine "a free passage forwards" and an opening "that will readily heal in spite of the urine passing through it." Mr. Harrison speaks of putting this teaching to a practical illustration and says: "My recollections of opening the urethra go back to the time before litholapaxy was invented—that is to say, prior to 1878. We opened the urethra in the median line to explore the bladder digitally and to take stones out of it more frequently than we do now. It rarely happened that a urinary fistula was the result. Whenever I met with such an accident I took some pains to ascertain how it had happened. It was unreasonable to suppose that there was no explanation for this in the face of its rarity. Thus it occurred to me to inquire whether the fistula had any obvious relation with what had gone into the bladder, or what came out of it. Was it due to the method of operating or to some disordered state of the bladder or urine, which rendered healing abortive? I came to the conclusion that it was the former. Because, if the perineal incision opened the urethra immediately in front of the prostate and within the horizontal portion of the urethra, as the patient was in the recumbent position, it seemed impossible to prevent the wound healing when required; whereas if the wound was made anterior to this point in the vertical portion of the canal, it was the reverse, healing was indefinitely postponed. This deduction admitted of easy proof, for assuming the opening to be in the median line of the perineum, though in the vertical portion of the urethra, all that was necessary to secure healing of such a fistula was with a probe-pointed knife to extend the incision in a downward direction, so as to throw the lower angle of the wound into the horizontal portion of the urethra as the patient lay in the recumbent position. Since I made this observation I have never troubled myself about opening the urethra when I thought it necessary either for the treatment of a stricture or the obliteration of a fistula, and other surgeons have verified this point.

Rowing for Women.—Lucille Eaton Hill, Director of Physical Training, Wellesley College, writes in the *Delineator* for August on the healthfulness of rowing for women—she says in part: "The freedom of skiff-rowing is most refreshing to mentally tense or nervous persons, who would chafe under the critical instruction and tire under the exactness of a crew's drill. On the other hand, the alert and rhythmical muscular action, the perfection of response of the muscles to the will in unison with others in the boat, has a fascination which is a real stimulus to those who can profit by crew rowing. The physical benefits which women derive from rowing cannot be exaggerated, provided they are willing to master the rudiments of the sport—for one must strive for good form, deep breathing, strength of back and chest, and wear no tight or stiff clothing about the waist. Correct rowing induces an erect carriage and finely poised head, a full chest and well-placed shoulders. Incorrect rowing disturbs all harmony of the figure. One can row one's self round-shouldered as easily as erect. Indeed, many girls lose the beneficial results they fancy they are gaining by rowing, through ignorance of a few simple fundamental principles of the exercise."

Dogs' Hospitals in Paris.—Such hospitals were first initiated in Paris and have flourished in that city to a greater extent than elsewhere. According to the *New York Herald* of September 21 the Sanitary Council of the Department of the Seine is causing trouble to keepers of dogs' infirmaries. By decree of December 1, 1866, dogs' hospitals were classified as insalubrious and inconvenient, and the opening of a dog infirmary is made conditional upon the accomplishment of certain formalities, including an inquiry to ascertain the views of inhabitants within a five-kilometer radius. This decree was treated as a dead letter as regards dealers, kennels, dogs' homes, and hospitals. Now, however, persons harboring colonies of dogs must conform to the law, the requirements of which are considered excessive.

Danger in Ice Cream.—The medical journals of London have often warned the public of the danger to health lurking in ice cream hawked about the streets. Now, according to the *New York Herald*, the report of the medical officer of health for the city of London abundantly proves the necessity for the regulations which in November come into force in the city for preventing the sale of poisonous ice cream. Out of twenty-three samples recently taken no fewer than twelve were found to be absolutely poisonous. Italians of the class who peddle ice-cream are never distinguished for cleanliness, and it thus may well be that much of that substance sold by them is, if not actually poisonous, at least not conducive to good digestion.

Smallpox in Montreal.—Since the commencement of the year Montreal has had some 500 cases of smallpox, with 11 deaths. Out of this total of 500 cases, 432 were unvaccinated.

SOIL POLLUTION AND TYPHOID FEVER.

TYPHOID fever is very prevalent at the present time in certain sections of Brooklyn. The outbreak is ascribed, according to the lay journals, to water polluted by drainage from Camp Black, occupied by soldiers during the Spanish-American war. It is thought that there may have been a seepage from the camp into Brooklyn's water mains. Hempstead, in which place Camp Black was situated, is in the center of Brooklyn's watershed, and typhoid was present, to some extent, among the soldiers when stationed there. A fact which makes it seem reasonable to suppose that this may be the correct explanation of the cause of the small epidemic, is that the disease only flourishes in those wards dependent on the regular water system for their supply. In the newer wards, which are independent of this system, the cases of typhoid fever are comparatively few. Thus it would appear as if the water were at fault, and that it may have been contaminated by leakage from Camp Black. Another reason which adds to the force of this view, is that during the past few months there has been an exceptionally heavy rainfall. In the Hempstead watershed are a large number of driven wells bringing the water to Brooklyn, and the rain may have carried the microorganisms of disease by natural methods.

The question of soil pollution by typhoid germs is one, however, by no means as yet clearly understood. Opinions differ as to the length of time the ground will carry typhoid bacilli undestroyed or undevitalized. If it be granted that such germs will live in the soil, with their destructive properties intact, for a period of years, then the theory put forth with regard to the cause of the typhoid fever now prevalent in Brooklyn is eminently reasonable. Further than this, an easy answer will have been given to the question of how many epidemics of typhoid fever have originated.

With reference to this point, "The Annual Report of the Medical Officers of the Local Government Board of Great Britain for Year 1900-1901," recently issued and published in the *Lancet*, gives some valuable information. Among the experiments undertaken none were of more practical importance than those with a view to elucidate the etiology of typhoid fever and the biology of the soil. Of the problems on which information was sought the first was, What are the precise conditions which, in a surface soil otherwise favorable to the multiplication of the typhoid bacillus, determine its prompt extinction when placed therein, in connection with the bacteria natural to the soil? Dr Sidney Martin, F.R.S., has for a considerable time been making extensive and minute researches into the matter, and in the report just issued has set forth the account of a series of experiments in continuation of his former investigations. The chief results hitherto obtained may be briefly summarized as follows: (1) In certain virgin soils the typhoid bacillus neither grows nor lives; (2) after cultivation these soils become capable, "when sterilized" of maintaining the typhoid bacillus for a limited time, (3) cultivated soils that is to say, soils containing organic matter—"when sterilized" support the bacillus for a long period and the bacilli spread through the soil"; (4) "unsterilized" cultivated soil—or, in plain language, ordinary garden soil—is inimical to the bacilli; the microorganism cannot be obtained from such soil after twelve days or so. As a result of his further studies Dr. Martin finds that the typhoid bacillus requires nitrogenous food. When proteids are present in the soil they are very slowly exhausted, and they enable the bacillus to live for a considerable time. Some of the bacteria which live in the soil, he believes, cause the disappearance of the typhoid bacillus. Dr. Martin is of opinion that it ought not to be inferred that the putrefactive bacteria cause the death of the typhoid bacilli "by destroying the nitrogenous matter and so exhausting the natural medium," or, to use more simple language, by starving them out. "Experiments have shown very definitely," he says, "that the products of putrefaction, soluble in alcohol, are very powerful agents in inhibiting the growth and in destroying the vitality of the typhoid bacillus." The bacillus, he maintains, is destroyed by the products of the putrefactive bacteria, which exist in most cultivated soils. The chief and practical point which is taught by these investigations is that the typhoid bacillus has usually a short life in the soil.

Therefore, if Dr. Martin's conclusions be right—and, as one of the greatest authorities on the subject, his opinions carry much weight—the land at Camp Black, to be capable of spreading typhoid fever after being impregnated with the germs of the disease so long ago as 1899, must come under the head of cultivated, sterilized soil—soil containing proteids.

Perhaps the promulgation of the theory that the present outbreak at Brooklyn is due to soil contamination at Camp Black, will spur investigators to look more closely into the question of soil pollution and typhoid fever. If so, the supposition will not have been advanced in vain.

MEDICAL SCIENCE IN THE NINETEENTH CENTURY.

THERE have been published recently, in the *Medical Times and Hospital Gazette*, a series of articles by Mr. W. Roger Williams, F.R.C.S. These form a résumé of medical science in the nineteenth century, and are interesting to a degree. A sketch of the more eminent medical men and pioneers in medical science, is given, together with an *aperçu* of the century's discoveries.

Matthias Schleiden is the first mentioned on the list, and although his fame has grown somewhat dim with the lapse of years, no one is more deserving of a prominent place in this gallery of great men. Schleiden was one of the first to make use of the microscope, and may be regarded as the founder of the cell theory and of vegetable morphology.

Schwann took up and carried on the work initiated by Schleiden, and was a pupil of a yet greater genius, the celebrated Johannes Müller, whom he assisted in the formation of his anatomico-pathological museum in Berlin. Müller was a dominating figure in the world of science, and his many-sidedness may be gathered from the fact that he taught human and comparative anatomy, physiology, embryology, and pathological anatomy, being at the same time director of the Berlin anatomical and zoological museum. Among his pupils were Virchow, Remak, Henle, Du Bois Reymond, and Helmholtz.

So much has been written of late concerning Virchow that it will be needless here to say much of the intellectual giant just dead. Mr. Williams says of him and the cell theory, "That the establishment of the cell theory gave an immense impulse to pathological research, which thus acquired a new and more definite basis; and a vast mass of new data rapidly accumulated." Some years later Rudolf Virchow pounced upon these *membra disjecta*, and, with wonderful insight, skill, and energy, he elaborated them—together with independent observations—into a kind of new cell theory of disease, much of which still survives."

The germ theory of disease is then treated at considerable length, and its origin and evolution is clearly traced.

The writer says: "So much progress has been made by means of modern methods of research, that it now seems probable the specific causative microbes of all communicable diseases will ere long be discovered."

A fitting eulogy is paid to Pasteur, and a list is given of his epoch-making discoveries. Renan's fine appreciation of the dead savant, when he said, "His scientific career is like a luminous trail in the great night of the infinitely little," is also quoted. To a consideration of Koch and his works Mr. Williams has devoted a large part of one of his articles, and gives a well-deserved meed of praise to the distinguished German.

With regard to Lister and the antiseptic treatment, the author remarks: "Thus it happens that out of the Listerian method of treating wounds there has now been evolved a new technique, based on later scientific discoveries, which may be called the aseptic method, since it aims at preventing infective diseases by precautions against the introduction of contagion *ab extra*. This plan has been elaborated in Germany, chiefly in Bergmann's clinic; and it has proved a decided advance on its Listerian predecessor.

Naturally, vaccination is fully dealt with, and in connection with this method Pasteur's remarkably eloquent explanation of the process is given, together with an account of his own discoveries with respect to vaccinating for anthrax, and other modes of "attenuation." Mention is made, too, of the fact that in many infections maladies Pasteur claimed to have proved that the microbe is not merely the means of spreading the infection, but that it is also the maker of the poison whence the morbid symptoms result.

Anæsthesia and its discovery are made the subject of a long article, in which due credit is awarded to the Americans who first found out the method. The oft-told tale of how Simpson discovered and tested the properties of chloroform is once again set forth. With regard to Simpson's selfish appropriation to himself of all the honor as the discoverer of anæsthesia, Mr. Williams says: "Simpson was, for a long time, regarded in Great Britain, not only as the discoverer of the anæsthetic properties of chloroform, but also as the inventor of anæsthesia. It cannot be said that he ever did anything to discourage this amazing display of popular ignorance. Honors and wealth were heaped upon him with more lavishness than discretion. He unhesitatingly took all the credit for his own achievement, as well as all that was due of this sort to Wells and Morton, for their immortal discovery. His conduct in this respect has been very properly stigmatized by Oliver Wendell Holmes as "unworthy of a man of his highly respectable position."

In the opinion of the author, the three greatest discoveries of the century just past were, firstly, the utilization of the microscope, to which we are indebted for the cell theory and the germ theory—the two greatest steps by which the science of medicine has ever advanced; secondly, the discovery of vaccination; and, thirdly, the discovery of anæsthesia. No one will be found bold enough to deny that these three discoveries were the most important made in medical science during the hundred years which ended with 1899. Perhaps the discovery of anæsthesia and of the cell and germ theory have been of the most benefit to the human race. Great, however, as have been the contributions to medical science in the time gone by, it may be confidently anticipated that the future will show results equally good.

Defective Development and Disease.

Dr. M. A. Veeder of Lyons, N. Y., read a paper bearing this title at the meeting of the American Microscopical Society held at Columbus, Ohio, in 1899, and which was subsequently published by that society. The paper, which was one of considerable value and scientific interest, treated the theme with special reference to the curability of consumption and cancer. These are, points out Dr. Veeder, the two types of disease, the one primarily due to defect of development, and the other to specific bacterial infection.

Speaking of consumption, the writer says that although this disease belongs in the class of bacterial diseases, yet, it has its developmental relations, having a marked predilection for the lungs and bony tissue. Referring to the predisposition of cattle to infection by the bacillus of tuberculosis, the writer says that while this is true, it does not affect the lungs in their case so frequently as in the human species, it depending in part, perhaps, upon the manner of their infection, and in part upon their manner of living. Normally, the temperature of the ox is somewhat higher than that of man, so that cattle are more readily infected for this reason. But growth of the bacillus in the lung would be retarded by their outdoor life at certain seasons, so that, as a rule, they succumb to tuberculous disease scattered in other parts of the body. Horses, on the other hand, are immune; their temperature, normally, being somewhat below that of man, and their lungs fully and freely expanded in the open air at frequent intervals, instead of being almost entirely disused, as in the case of cattle confined to their stalls for weeks and months together, and at best only walking slowly about in the open air. As a matter of fact, cattle that run wild on the plains are as free from tuberculosis as horses. Lecturers at dairymen's conventions who tell the farmers that they must keep their cattle warm if they would secure record yields of milk and butter, are responsible for much of the spread of tuberculosis.

Dr. Veeder draws attention to what he and many others consider a serious menace to the general health, namely, the frequency of tuberculosis among the barn-yard fowl, and goes on to say: "The prevalence of tuberculosis among graminivorous birds, whose temperature is normally 105° is very significant from the point of view of the present discussion. Their flesh is not eaten raw, nor do they yield milk, so that there is no great danger to the human species from tuberculosis in fowls, but their droppings falling into the hay and grain become a source of great danger, especially to cattle, whose intestinal tract is most liable to infection from this source. Indeed, this may be the explanation of the reinfection of herds on farms where they have been slaughtered, wholly or in part, in response to the tuberculin test."

This is an ingenious suggestion and reads as if it had the ring of truth, and it may—as Dr. Veeder says—become possible to prevent tuberculosis in cattle, as well as in the human species, by proper outdoor exercise of herds and prevention of infection from such sources as fowls.

THE MEDICAL SERVICE OF THE MERCHANT MARINE.

A correspondence has been carried on recently in the *Lancet* concerning the treatment received by the medical men of the merchant marine. Several letters have passed through the correspondence column of our contemporary, and the expression of views has been interesting, though somewhat divergent. One gentleman states that nearly every international passenger-carrying steamer of certain capacity is compelled to carry a medical officer, who is bluffed by the company into accepting for his services the pittance of $40 to $60 per month on English and American ships, $20 to $50 on German boats, and about the same amount when sailing under other flags, and as they are seldom allowed to charge a fee for their services, their pay barely covers the cost of uniforms and other items of expense. On American ships their position is humiliating, as the engineers, deck officers, and freight clerks receive better wages and are judged accordingly.

Another physician writes to say that he considers medical officers of the merchant marine are well off, that the pay of $50 a month is sufficient, and that, on the whole, their lot is a happy one, while yet another medical man traverses this statement with much vehemence, declaring that not only is $50 a month miserable pay, but that some of the Atlantic lines give but $30 a month in the winter, while an advertisement appeared lately offering a surgeon $20 a month to go to Australia and back. This latter writer recommends that the following conditions be insisted upon by qualified medical men before accepting posts as ship's surgeons: (1) that the surgeon be paid a minimum salary of $50 a month, for which he will attend the crew and steerage passengers; (2) that he will be at liberty to charge fees for attendance on first and second-class passengers; and (3) that he have a stateroom in a suitable place for himself, quite distinct from a consulting room or dispensary.

Undoubtedly, ship surgeons have grave causes for complaint, and the above conditions would be by no means too onerous for the steamship companies to fulfill without placing any undue strain upon their resources.

THE EFFECT OF AN ARCTIC WINTER UPON THE NERVOUS SYSTEM.

In *The Sun* of October 5 Dr. Frederick A. Cook of Brooklyn tells of the manner in which the Arctic night effects the disposition of those who pass through it. He says: "The long Polar night is one of the barriers to the success of every Polar expedition. This night of months, with its low temperature and high humidity, drives men to the verge of desperation. It depresses the spirits and suppresses all of the functions of the body. Now one is melancholy, then one cusses one's self and companions, and again a wave of sleepy dulness covers every human effort. Indeed, this hellish darkness brings out all of the badness of which a man is capable."

The isolation, the monotony, the chilling cold produce a depression of spirits which in some men ends either in madness or a condition bordering on that state. The mind reacts on the body and the body on the mind. It therefore requires a man of exceptionally strong constitution and will, and with sanguine temperament to make a successful Arctic explorer.

De Long, an Arctic explorer at the head of an expedition which went away on the *Jeanette* in 1879 and was ice-bound on her for a year, has left a record in the shape of a diary of his mental sensations and those of his crew. This diary—which survived its writer—is the most realistic and melancholy description of a sojourn under the Polar sky ever penned. It enters fully into every phase of the situation, and toward its close affords practical proof of how an intelligent, educated man, physically sound, can lose his mental poise under the depressing conditions of a year spent in the Arctic regions.

Dr. Cook asserts that if the log of any Arctic expedition be examined before it is revised it will be found that the thoughts of the writer often have no logical beginning and ending.

A body of men who lived together in close companionship for a considerable period of time, knowing that they could not escape each other's company if they wished, would many of them, probably, develop feelings the reverse of amiable toward their companions. There is, then, no need for wonder when we hear that the members of an expedition to the Polar regions become irritable, quarrelsome, and sometimes mentally affected. Physiologically, it is only exactly what might be anticipated, although to a student of human nature the consideration of men placed in such circumstances would be a matter of interest—perhaps, even of instruction.

EXPERIMENTS WITH REGARD TO DIGESTION.

Professor Pawlow has been recently undertaking experiments for the purpose of investigating as to the comparative digestibility of various kinds of food, and has obtained some interesting and remarkable results. Dr. Romme has described these experiments in *La Revue* for August. In the main these were as follows: The gullet of the animal was cut in sections and fixed to the neck, so that when it ate the food merely fell to the ground. The stomach was divided into two parts, one into which no food was allowed to penetrate, while into the other was placed the food necessary to keep the dog alive.

According to the writer in *La Revue*, the experiments showed that the offering to the dog of food which he liked caused an abundant secretion of gastric juice, although nothing had entered the stomach. If he were offered a tid-bit, the flow of gastric juice was much more abundant than if he were given food which he merely liked, showing that appetite is needed to set the gastric juices working properly. Thus, Pawlow's experiments have proved that when eating without appetite the food was either not digested at all or very badly digested.

The investigator also says that he has shown that the brain transmits its orders to the stomach by means of two pneumogastric nerves. These nerves were cut on a specially "prepared" dog. Then the dog was given raw meat, which did not reach the stomach; but no gastric juice whatever was secreted. No method of mechanical excitement produced juice. And, further, if bread or cooked white of egg were introduced, into the stomach—the dog being unconscious that such was the case—the food remained for hours without causing the least secretion of gastric juice. But after administering extract of meat or milk first, the secretion would be provoked. The conclusions which Dr. Romme draws from the foregoing experiments are that in the poorer classes a man lives far more from his muscles than from his brain, hence the desire for food. It is rather a healthy sign to be somewhat greedy. The reason that dyspepsia is so common among men of letters and the like is that their brain is so much occupied with their work that they eat without thinking of the food taken. The pneumogastric nerves have not been called into action, and in consequence the gastric juice is badly secreted. It is, therefore, not conducive to good digestion to be absorbed in a book or newspaper at meals.

In the case of consumptives with little or no appetite and insane persons, who often refuse food, the gastric juice may be set in motion by taking milk or broth an hour or so before a meal.

The Operative Treatment of Appendicitis.

When to operate in appendicitis has been the bone of contention among surgeons, on this and the other side of the Atlantic, for some time.

The recent operation upon the King of England was the means of bringing the subject prominently to the front once more, and the matter has been argued vigorously by the upholders of both procedures.

At the Belgian Congress of Surgery, which opened at Brussels on September 8, one session was devoted to the discussion of the treatment of appendicitis. Dr. Broca (Paris), in conjunction with Dr. Gallet (Brussels), presented a paper dealing with their experience of the disease, and expressing a strong preference for operating, whenever possible, during a quiescent period, and not during an acute attack. The paper, however, which aroused the greatest interest was that contributed by Dr. Sonnenberg of Berlin, who gave the results of 1,200 operations that he had performed, within the past twelve years, at the Moabit Hospital, Berlin.

The most valuable information given by Dr. Sonnenberg was a narration of his experience with regard to the diagnosis of appendicitis. He laid peculiar stress upon the importance of observations respecting the augmentation of the white blood-corpuscles (leucocytosis), which he said bore a remarkable relation to the gravity of the lesions in appendicitis, and to the reaction of the peritoneum. In many conditions, leucocytosis afforded a diagnostic element of great importance, more trustworthy than the pulse and temperature, as an indication when to operate.

Dr. Sonnenberg agreed with Dr. Broca in advocating operation during the quiescent period whenever possible, and the verdict of the majority of the surgeons who took part in the discussion was in unison with these views.

News of the Week

German Hospital, Philadelphia.—Dr. Carl Frese, for fourteen years superintendent, has resigned. Dr. Henry Page is serving as acting superintendent.

University of Pennsylvania.—Dr. J. L. Gates has been elected assistant demonstrator of pathology, Dr. Hidaya Noguchi assistant in pathology, Dr. John T. Carpenter instructor in ophthalmology, and Dr. A. W. Jarman demonstrator of prosthetic dentistry.

Pathological Society of Philadelphia.—At a stated meeting, held October 9, Dr. Charles W. Burr read the address of President, reviewing the work of the society for the fiscal year just ended. He pointed out the change in the character of the work done by the society, the substitution, in a large measure, of histologic studies for gross specimens of morbid anatomy, and to the prominent place taken by investigations in the field of pathologic chemistry. He made an appeal for the exhibition of fresh specimens, which, though they might seem commonplace to the pathologist, would still be instructive and interesting to the clinician, who represented a not inconsiderable and not unimportant contingent of the society. The Recorder, Dr. David Riesman, presented his annual report, in the course of which he recited the successive stages through which the publication of the proceedings of the society had passed. He pointed out the success that had attended the present method of publication in the form of periodic fasciculi, which insured prompt publicity and distribution for the scientific work of the society. Dr. Thompson S. Westcott read the report of the treasurer, showing the state of the finances of the society. The election for officers resulted in the choice of Dr. Charles W. Burr for president, of Drs. Alfred Stengel, Joseph McFarland, Simon Flexner, and Mazyck P. Ravenel for vice-presidents, of Dr. J. Dutton Steele for secretary, of Dr. Thompson S. Westcott for treasurer, and of Dr. David Riesman for recorder.

Philadelphia County Medical Society.—At a stated meeting, held October 8, a symposium on Chronic Nephritis was presented. Dr. James Hendrie Lloyd read a paper on "The Nervous Symptoms in Chronic Forms of Nephritis." These he divided into regional and general. They included together headache, convulsions, paralysis, aphasia, amaurosis, and neurasthenia. He emphasized the importance of systematic examination of the urine, without which no diagnosis could be considered complete. Dr. George E. de Schweinitz read a paper entitled "The Ocular Manifestations in Chronic Bright's Disease." He discussed uræmic amaurosis, retinitis, and neuroretinitis, angiosclerosis of the fundus of the eye, and subconjunctival hemorrhages. Dr. James M. Anders presented a communication entitled "Treatment of the Nervous Phenomena in

Chronic Nephritis." He considered at first the dietetic indications and, subsequently, the symptomatic indications for drugs and other therapeutic measures. Dr. Samuel D. Risley continued the discussion on the ocular manifestations, citing illustrative cases. Dr David Riesman referred further to the nervous manifestations, speaking especially of hemiplegia and aphasia, of transitory uræmic mental confusion, and suggesting the possibility of chronic insanity of uræmic origin. Dr. L. Webster Fox made some additional remarks on the ocular manifestations. Dr Hobart A. Hare referred to the usefulness of venesection and intravenous infusion, and of morphine in the presence of acute uræmia, of the danger of pilocarpin, while he saw no advantage in skimmed milk and no difference between red and white meat in so far as the kidneys were concerned. Dr. Charles W. Burr dwelt on the difficulty in diagnosis of the uræmic and the apoplectic state, and pointed out the variability of the symptoms in the former as compared with the latter. Dr. Augustus A. Eshner referred to cases in which albuminuria, and even tube-casts, could not be found on repeated examination of the urine, and the diagnosis had to be made from the ocular findings and the cardiovascular conditions. He spoke also of cases of renal inadequacy in which the amount of urine and, correspondingly, the amount of urea eliminated were greatly reduced, without the presence of albumin or tube-casts in the urine, and without the discovery after death of the lesions of nephritis. Dr. Charles P. Noble stated that albumin and tube-casts were found in a considerable proportion of the large number of cases that came under his observation, principally for the relief of surgical disorders, but in which other symptoms of nephritis were not present, and did not subsequently appear. He pointed out the frequency with which albumin and tube-casts were found in the urine in the sequence of operations on or about the kidneys.

Vermont Society for the Study and Prevention of Tuberculosis.—Under this name an association was recently established at Burlington, Vt., by a number of physicians and laymen. At the organization meeting a constitution was adopted, resolutions relative to the establishment of a State sanatorium and to supporting the work of the State Cattle Commission were passed, and various phases of the tuberculosis question were discussed. The following officers were elected: *President*, Hon. E. C. Smith of St. Albans; *Vice-Presidents*, Drs. Don D. Grout of Waterbury and C. W. Peck of Brandon; *Secretary*, Dr. H. E. Lewis of Burlington; *Treasurer*, H. L. Stilson of Bennington; *Executive Committee*, Dr. H. D. Holton of Brattleboro, W. N. Platt of Shoreham, Henry Ballard of Burlington, and E. H. Ross of St. Johnsbury.

Discussion on Typhoid Fever at the Academy. At the meeting of the Medical Section of the Academy of Medicine, to be held on Tuesday, October 21, there will be a symposium on typhoid fever, under the several heads of etiology and prevention, symptomatology and clinical diagnosis, laboratory aids to the clinician, the chemical nature of the typhoid bacillus, and treatment. Following these papers there will be a general discussion. The chairman of the section is Dr. James K. Crook, and the secretary, Dr. E. E. Smith.

The Milk Supply of Chicago.—In the Bulletin of the Chicago Health Department for the week ending October 4, it is stated that the milk supply of the city was never better than it has been for the past month. "The week's examinations show only 3.5 per cent. of the samples below the ordinance standard. Watering and the use of formalin as a preservative have become 'lost arts.' The summary sewer disposal of milk thus adulterated has taught all concerned that the practice is not profitable. The most marked improvement has been in the quality of restaurant milk and cream. When the increase of typhoid compelled the department to resort to drastic measures, restaurant samples averaged 17 per cent. of watered or formaldehyded. Last week every sample taken from a restaurant or hotel was sound and fully up to or above the standard."

College of Physicians of Philadelphia.—At a stated meeting, held October 1, Dr. Thomas C. Ely read a paper entitled "Hodgkin's Disease, with the Report of a Case." The patient was a child of three years, and it presented the classical, clinical picture, being remarkable especially for the early period of life at which it occurred. Evidence was presented suggestive of the tuberculous character of the disease. Dr. Charles H. Frazier made a presentation of a patient one year after division of the sensory root of the gasserian ganglion for the relief of tic douloureux; no Recurrence. The operation had been suggested by Dr. Wm. G. Spiller, to obviate the dangers of removal of the ganglion itself. The success of the operation depends upon the failure of the divided sensory root to regenerate. This was first demonstrated on lower animals. Next the technique of the operation was perfected; and, finally, the procedure was applied to the living human subject. The patient was a man who, for several years, had suffered from trigeminal neuralgia, and had previously been operated on by division of the painful nerve. Sensibility and pain recurring, the division of the sensory root was effected, and there has since been no return of sensibility in the distribution of the fifth nerve on the affected side, and likewise no recurrence of pain. The operation is, therefore, looked upon as a success, although not more than a year has elapsed since the performance of the operation.

Philadelphia Hospital.—Dr. G. E. Pfahler has resigned as assistant chief resident physician in the Philadelphia Hospital, and Dr. Wm. M. Capp has been elected to fill the vacancy.

Physical Tests Demanded of Railroad Employees.—At the instance of Dr. B. F. Clark of Cincinnati, chief surgeon of the road, the management of the Baltimore & Ohio Southwestern Railroad has determined upon a more rigid physical examination of the applicants for employment as trainmen. In addition to the usual tests for color blindness it is proposed to establish a standard of physical health approaching, if not equalling, that of the army and navy.

Indiana's Medical Law Sustained.—The Supreme Court of Indiana has decided in favor of the constitutionality of the medical act of 1901. This act goes further than the one of 1897 in defining what constitutes the practice of medicine, and its intent is to suppress the horde of healers and professors and scientists who claimed exemption on the score that they were not medical practitioners.

A Clergyman Fined for Illegal Practice of Medicine.—The Rev. W. N. Ritchie, a Presbyterian clergyman, was recently found guilty of practising medicine illegally, and was fined $75 in Special Sessions. He was secretary of a company formed to exploit an alleged cure of the morphine and other drug habits, which he owned. The prosecution was on the complaint of the Medical Society of the County of New York.

A Contrast.—An American graduate in dentistry, formerly practising in Philadelphia, was the assistant of one of the leading dentists of Vienna up to a few days ago, when the authorities fined him and expelled him from the country for having pulled a tooth. The Austrian law permits a foreigner to act as an assistant to a dentist, but not to perform any operation. At the same time that this occurred, an Austrian surgeon was operating freely in America, and when some one suggested that he was breaking the law, the medical examiners courteously gave him a private examination and presented him with a certificate of qualification.

The Southern Surgical and Gynecological Association will hold its fifteenth annual meeting, under the presidency of Dr. W. E. B. Davis of Birmingham, Ala., in Cincinnati on November 11, 12, and 13, 1902. The railroads have promised a one and one-third rate on the certificate plan. The secretary of the association is Dr. W. D. Haggard of Nashville, and the chairman of the committee of arrangements, Dr. Thaddeus A. Reamy of Cincinnati.

Fined for an Incorrect Diagnosis.—A man in Richmond Borough recently brought suit against a physician in New Dorp for $5,000 damages, alleging that the physician had incorrectly diagnosed the illness of the plaintiff's daughter, as a result of which she died. It was affirmed that when the defendant was called to see the child he said she had bronchopneumonia, but another physician, called later, diagnosed the case as one of diphtheria. The accused physician contended that the first diagnosis was correct, and that the diphtheria was a later development. The court found against him, however, and awarded the plaintiff $500 damages. The case will be appealed.

Cholera and Dysentery in a Transport.—The army transport *Sherman* arrived at San Francisco from Manila on October 10, and was detained in quarantine because of the presence of cholera. There had been some deaths from that disease during the voyage and several from dysentery.

The Plague in Russia.—Some apprehension has been caused by the persistence of the plague in Odessa and other towns in the southern part of Russia, despite the earnest efforts of the sanitary authorities to eradicate it. The disease not only persists, but is becoming more severe, often running its course to a fatal ending within twenty-four to thirty-six hours.

Philadelphia County Medical Society.—At a stated meeting, held September 24, a symposium on typhoid fever was held. Dr. Roland G. Curtin read a paper entitled "Hemorrhage in Typhoid Fever," discussing the cases in which the bleeding takes place from the intestinal lesion and also those in which extravasations of blood take place from numerous mucous surfaces, and into the submucous and subcutaneous connective tissues. In his experience the mortality in cases presenting this complication is lower in private than in hospital practice, and it seemed to him that such hemorrhage is more frequent in patients that have been subjected to cold bathing. In the way of treatment ergot, adrenal preparations, the introduction of ice into the rectum, the administration of opiates and of oil of erigeron were found most serviceable. Dr. Herman B. Allyn presented a communication entitled "The Significance of Abdominal Pain in Typhoid Fever." He recited the various causes of such pain, dwelling especially, however, upon that associated with cholecystitis and with perforation of the bowel. Dr. Robert G. Le Conte read a paper on "The Operative Treatment of Typhoid Perforation." He made a plea for early diagnosis and prompt operation and described the several plans to be pursued in accordance with the conditions present. Dr. Wm. Egbert Robertson read a paper entitled "Feeding in Typhoid Fever." He bespoke a more generous diet than it is the custom of most clinicians to permit, in order the better to combat the toxæmia of the disease, and to avert the wasting and the asthenia, together with complications arising out of them. The discussion was participated in by Drs. G. G. Davis, H. A. Hare, N. Price, J. H. Gibbon, B. F. Stahl, and W. L. Rodman.

Shortage in the Army Medical Corps.—Although there are forty vacancies in the Medical Department of the United States Army, and an examining board has been in session in Washington for some time, only five applicants have been accepted out of all who offered themselves. Complaint is made that the examinations are too severe, and that a man must be above the average of the recent graduate to pass them successfully. It is true that the standard is very high, but it is not so high that men in plenty could not be found to fill the vacancies if there was any temptation for them to enter the army. We have several times discussed the changed conditions in the Army Medical Corps, and now this serious crippling of that corps sustains our contention that Congress made a fatal blunder when it meddled with this all-important branch of the service.

The Medical Society of Virginia.—At the thirty-third annual meeting of this society, held recently at Newport News, the following officers were elected: *President*, Dr. John N. Upshur, Richmond; *Vice-Presidents*, Drs. Wm. F. Cooper, Newport News; R. W. Sanders, Max Meadows, and Junius F. Lynch, Norfolk; *Recording Secretary*, Dr. Landon B. Edwards, Richmond; *Corresponding Secretary*, Dr. J. F. Winn, Richmond; *Treasurer*, Dr. Richard T. Styll, Newport News. Dr. Wm. S. Christian, Urbana, was chosen to deliver the "Address to the Public and Profession" at the next annual session.

Foreign Physicians in Peru—Under date of July 18, 1902, Consul Charles V. Herdliska of Callao, in reply to an inquiry regarding the chances of success for an American physician in Lima, writes as follows: "Before a physician can enter upon the practise of his profession in Peru he must pass a State examination upon medicine, conducted in the Spanish language. Upon being found qualified, a certificate is issued which entitles him to practise his profession in any part of the Republic. The opportunities for American physicians would seem to be good. Both Lima and Callao contain quite a large American and English colony, and the Peruvians themselves appear to have great faith in the American, English, German, and French physicians and surgeons, on account of the advanced state of medical science in those countries."

Professor Adolf Lorenz of Vienna arrived in Chicago last week, and since that time his doings have been widely chronicled in the daily papers. On Sunday he performed the operation for which he was called from Vienna. On Monday he repeated the operation on nine children at a clinic in the College of Physicians and Surgeons, and on Wednesday evening he operated on several more children at the Mercy Hospital, and delivered a lecture on "the principles of the bloodless reduction of congenital dislocation of the hip-joint." According to his statements to the reporters, Professor Lorenz has perfect confidence in the success of his operation, and confidently predicts that all the children with congenital dislocation of the hip, upon whom he performed his manipulations, will be cured of the deformity. "I regret," he said, on beginning the clinic at the College of Physicians and Surgeons, "that I shall not have the opportunity of proving to you that the cases I am about to operate on for unilateral and bilateral congenital distortions of the hip are to be cured permanently by the operation. They are so cured in every instance I have had the opportunity of demonstrating in Rome, Berlin, Moscow, Hamburg, and Vienna, but by the time the little limbs are free of the bandages and fit for use, I shall be back in Vienna." And to the reporters who questioned him as to the outcome of his private operation on Sunday, he said, after giving a detailed description of his method of treatment of congenital dislocation of the hip in general, and of how he had treated the little Armour child in particular, "To-morrow I shall allow her to sit up; in a couple of days I shall require her to take exercise, and that exercise, assisted by nature, will bring about the junction of bone, so that when the cast is removed the hip will be found to perform its function in a perfect manner.. The leg operated on will be exactly the same length as the other, and that hip will then be as perfect as the other, or as that of any normal body."

Obituary Notes.—Dr. Jane K. Carver died at Hill Crest on the South Mountain, at Graffenberg, Pa., on October 9. She was a daughter of the late Judge Francis Kimmel of Chambersburg, Pa., and the widow of Dr. Charles Carver. She had been in charge of the woman's department of the State Hospital for the Insane at Harrisburg for many years.

Dr. ELVIRA RAINIER, one of the leading woman physicians in this State, died at her home in Oswego, N. Y., on October 13, at the age of fifty-five years. She was born at Coldwater, Mich., and was graduated from the Woman's Medical College of Pennsylvania in the class of 1877. She was a member of the Central New York Medical Association, secretary of the Oswego County Medical Society, and consulting physician to the Oswego Hospital.

Dr. EDWIN A. W. HARLOW died at his home in Quincy, Mass., on October 12, at the age of eighty-eight years. He was a member of the Harvard class of 1841. He retired from practice on account of his age several years ago.

Dr. HENRY HORACE LYNCH died at his home in Jersey City, N. J., on October 12. He was born in Woodbridge, N. J., and was graduated from the New York University Medical School in 1878.

Dr. OBADIAH C. BRICKLEY died at York, Pa., on October 2. He was a pension examiner from 1894 to 1898, and served three terms as coroner. He was also prison and almshouse physician for a number of years.

Dr. JOHN PACE MUTCHLER died at Stroudsburg, Pa., on September 29. He was a graduate of the Jefferson Medical College in the class of 1875.

Dr. HARPER B. LACKEY of Scranton, Pa., died in Philadelphia on September 30, at the age of fifty-eight years. He was a graduate of Bellevue Hospital Medical College in the class of 1868.

The Berlin Academy of Sciences has announced that its academic prize of 5,000 marks will be awarded, in 1904, for an investigation of the cathode rays, and in 1905 for an investigation of the theory of functions of several variables which admit of linear substitution. The income of the Cothemus legacy—$2,000—for 1904, will be awarded for investigations of new varieties of grain. The papers may be written in English, and must be presented, without the name of the author, to the Bureau of the Academy, Universitätstrasse 8, Berlin.—*Popular Science Monthly.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE ELECTION—WELL-TO-DO HOSPITAL PATIENTS—NEWSPAPER CORRESPONDENTS—RISKS IN CREAMERIES—PHTHISIS IN ASYLUMS—POISONOUS FOOD—VACCINATION FEES.

LONDON, September 26

SIR VICTOR HORSLEY has been re-elected to the General Medical Council by more than double the number of votes given to his opponent. This shows plainly enough that Mr. Smith had no chance, and to some extent justifies those who inveighed against him for putting the profession to the trouble and expense of an election. But the election also exhibits the apathy of the profession, or its hopelessness of the council. The votes were 7,672 for Sir V. Horsley, and 3,105 for Mr. Smith, a total of only 10,777—a very small poll, considering that the voter had only to sign the paper and post it. There are more than 6,000 practitioners in London, more than 16,000 in the provinces of England, and more than 1,000 in Wales. Scotland and Ireland are not in this election. How is it that, with all the whipping up, less than half the voters will take the trouble to sign a paper?

The subject of well-to-do hospital patients has continued to furnish letters to the newspapers. Perhaps the dead season may account for their admission, as well as some other subjects of medical interest. In this case we may hope that the influence will be beneficial. Too many of the correspondents harp on the high fees expected by surgeons, and when they mention a sum it is invariably one which very few are in a position to obtain. It has been well pointed out several times that the juniors among our hospital surgeons do not expect such fees, but are just as well able to operate.

When a man has reached the highest rung of the ladder, he, of course, considers himself entitled to the highest fees, especially as he can only get through a certain amount of work. He is, in fact, generally obliged to pass on some cases to his confrères. But why should the poor man insist on having the most fashionable surgeon? If he would be guided by his ordinary attendant, he could have the services of a surgeon whose fee he could pay, and one, too, whose hospital duty continually included similar operations. Again, the "well-to-do" patient, as he has been called, need not go to a luxurious or extravagant nursing home. Many would be as well and many better in their own homes, under the eye of their own family doctor, who would conduct the after-treatment. Many of these family practitioners could, indeed, undertake various operations without more help than his neighbor would give. If they desired a consultant's views as to the necessity of operating—well, that could always be obtained from the most eminent surgeons. And here, again, it may be said that the most brilliant operator is not necessarily the person whose surgical judgment is most trustworthy.

Unquestionably, many minor operations, which should fall to the general practitioner, pass away to consultants and the nursing homes which they recommend. Some of these are very luxurious and very costly. Many are not only recommended, but practically owned by surgeons. As to this, I was told a story the other day, which might teach a lesson to some:

A patient, who had returned cured from one, told me he did not go to the one he formerly resorted to. Asked if it were unsatisfactory he said no, but it seemed to be run by the surgeon, and, therefore, he would not go, as he did not approve of eminent surgeons carrying on the commercial element.

I notice that the correspondents who write to defend surgeons' fees and nursing homes are content to use a *nom de plume*. On another subject, which has crept into the newspapers, "cancer research" several take care to give their names and addresses—no doubt "as a guarantee of good faith," as editors say. Could you suppose any other motive for airing very opposite views? But the "views" of most of these writers are scarcely worth attention.

The Annual Report of the Irish Local Government Board contains further illustrations of the part played by milk in disseminating disease. During the year there were five outbreaks of typhoid fever in different districts in Ireland, traced to creameries. This confirms what has been the result of previous investigations.

The milk sent to the creameries is mixed. If that from one dairy is infected, the consequence is serious to the various families sending their milk to the creameries, among whom the "separated milk" is afterward distributed. In the appendix to the report, Professor MacWeeny, bacteriologist to the Board, has a paper on the subject, in which he urges the necessity for the Pasteurization of creamery products.

A committee was appointed by the Medico-Psychological Association, some two or two and a half years ago, to inquire into the prevalence of phthisis in asylums. The report has just appeared, and states as "a fact beyond contradiction, that phthisis is prevalent in our public asylums to an extent which calls for urgent measures." The committee further state that many patients contract the disease after admission to the asylums.

The character of the population of the asylums has much to do with this acquired phthisis, for the death rate from this disease is twice as high in those filled from urban than from rural districts.

Many of these patients are discharged every year, and a great number of the staffs migrate from place to place, and the committee suggests that there is a risk of dissemination of the disease by these persons. The prevention of overcrowding, and the isolation of phthisical cases are obvious precautions.

An outbreak of poisoning, traced to eating pork pies from a shop in Derby, has caused much uneasiness. It was supposed, at first, to be due to ptomains, and Professor Delépine's report was looked forward to with interest More than 200 persons were affected in various parts of the country, to which pies were sent or taken from one particular batch. An adjourned inquest on one of the fatal cases was concluded on Tuesday, when Professor Delépine reported that he found bacilli in deceased's stomach, which might produce all the symptoms from which the various victims suffered. He found these bacilli also in the pork pie submitted to him. He believed the meat was good, but became contaminated during preparation, and that it would be impossible for the vendor to notice anything wrong.

Dr. Howarth, M.O.H. for Derby, testified that the vendor was a careful tradesman, as to whom no complaint had ever been made. As the outcome of the inquiry, he should make some recommendations to the corporation with a view of minimizing such risks. The jury returned to the effect that deceased died through eating contaminated pies, and exonerated the maker from all blame. The bacillus detected by Professor Delépine belongs to the colon group, but differs in some respects from Gaertner's bacillus. Perhaps it may be the same as that which caused an outbreak of meat poisoning at Friedeberg. It may have been conveyed in dust for some distance, but there is a suspicious place rather near. It was fatal to animals, and found in their blood. It multiplies very rapidly at ordinary temperatures, broth being rendered turbid by it in two hours. It was found in the jelly of the pies, and this is naturally the most dangerous ingredient, as it is usually poured in last, and it melts at a low temperature, thus providing a fertile soil for bacillary growth It makes no change in the taste or smell of food contaminated with it. Clearly this case is not properly spoken of as ptomain poisoning. Further, it shows the dangers that lurk in small, private slaughter-houses, and suggests their closure.

Local authorities are finding out that neglect of vaccination does not pay. The Edmonton guardians on Wednesday resolved to petition the Local Government Board to reduce the fees of public vaccination, though their chairman told them that possibly, if the acts had been properly carried out, the expenditure of £10,000 to £12,000 in dealing with the smallpox might have been saved. It was said that about £3,850 had been paid to four public vaccinators, one of whom received £1,110 Similar object lessons will, no doubt, be talked of, and may prove useful.

In contrast with the foregoing it is pleasant to report a case of appreciation of a medical officer of health: The Lambeth Council on the 18th of September unanimously voted to Dr. Priestley an honorarium of 100 guineas in recognition of his energy and skill in combating the epidemic of smallpox.

Improvement of the Condition of the Insane. At the conference on the improvement of the insane, which met recently in Antwerp, the following resolutions were adopted: (1) That the confinement of the insane henceforth be abandoned, except in the case of those recognized as dangerous; (2) That the system of boarding insane persons with families be carried out whenever possible; (3) That it is expedient to renew the wish formulated at the congress at Paris for the establishment of schools for special classes of the mentally weak under medical supervision; (4) That the manner of placing patients be left entirely to physicians; (5) That forcible restraint should be condemned.—*Science.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 9, 1902.

The Modern Operation for Radical Cure of Umbilical Hernia.—W. H. Conant says that umbilical hernia in children, as a general rule, gets well with the use of a truss. Strangulated umbilical hernia is to be operated on like any other hernia. Radical umbilical hernia is to be operated on if the patient will give consent. Otherwise, a well-fitting truss should be worn day and night. Irreducible hernia is to be operated on unless there is some marked contraindication, like serious kidney or heart lesion. Age and size of tumor need be no bar to an operation. The operation is to be preferred which will combine rapidity with diminution of shock, both by diminishing the hemorrhage and also the length of time that the patient has to be under an anæsthetic. Where ether is contraindicated, cocaine should be used.

Ultimate Results of Operations for Appendicitis.—Homer Gage states that he has been able to trace the subsequent history of 228 out of 300 cases operated on by him for appendicitis. Forty-two have complaints of some kind to make—thirteen of discomfort or soreness, two of the non-closure of fecal fistulas, nineteen of a hernia through the scar. Among the favorable replies, sixty found their general health and digestion very much improved since the operation. In one this improvement did not begin until three months after the operation, in one it was observed a year later, and in a third was not marked until three years later; the last two cases probably belong with the great majority who were relieved of their immediate difficulty, and whose general health remained as before the appendix became inflamed. Their late improvement was very likely wholly independent of their surgical experience.

Massage in Fracture Treatment.—Edward A. Tracy says that in cases of fracture the surgeon commences by removing what he can of obstructive material. To do this he begins at the end of the swollen tissues nearest the heart, grasping the limb in his two hands and giving the tissues a gentle but firm squeeze. He relaxes his grasp, and again grasps and squeezes about a half inch below, and so on until the lower border of the swelling is reached. After this has been repeated two or three times consecutively, the limb can be held at its distal extremity by one hand, while a pressure stroke along the limb is made with the other hand in the direction of the blood flow. Massage may be applied from the commencement of attendance on a fracture case. It removes obstruction to the circulation, hastens the absorption of exudates and tissue detritus, increases proliferation of cellular elements by the stimuli of increased nutrition, prevents muscular atrophy for the same reason, and speeds the reunion of the bony fragments. A wood-plastic splint moulded upon the parts is in every way superior to plaster-of-Paris.

Journal of American Medical Association, October 11, 1902.

Uræmic Aphasia.—D. Riesman offers the following conclusions: (1) Aphasia may occur in uræmia, and is, at times, the sole expression of that state. (2) It may be a precursor of uræmic convulsions or coma. (3) It is frequently associated with right-sided motor paralysis, hemiplegic or monoplegic in character. (4) It is usually of a motor type, but may be sensory. There may be word blindness and word deafness. It may be associated with agraphia, even when there is no paralysis of the limbs. (5) It is comparatively frequent in children, particularly in cases of post-scarlatinal nephritis. In adults it may occur in any form of Bright's disease. (6) It is generally transient and has a marked tendency to recur. (7) When paralysis is present the two may disappear simultaneously; the aphasia usually disappears first. (8) The features of uræmic aphasia are, *per se*, not characteristic of the causal condition. (9) The most important diagnostic features are the transitoriness of the aphasia and the presence of other uræmic symptoms or of signs of nephritis. (10) In every case of sudden aphasia the possibility of its being renal in origin should be considered, and careful studies of the urine and of the system at large should be made with this thought in mind.

The Surgery of Rickets.—H. L. Taylor offers the following rules of procedure: (1) Subcutaneous osteotomy of the shaft is a safe and certain operation for the correction of knock-knees and bow-legs. (2) It is nearly always to be preferred to cuneiform osteotomy, osteotomy into the joint (for knock-knees), or operation by the open method. (3) The risk of non-union of bone or other accidents, with asepsis and an experienced operator, are slight, and not increased in rickety subjects. (4) The commonest errors are imperfect correction, especially failure to overcome inversion of the feet, and relapse from improper dressings, or from operating before the subsidence of the rachitic process. (5) Plaster-of-Paris makes an excellent splint, completely controlling the position of the fragments when properly applied. Plaster or other splints should be worn for some months. (6) Subcutaneous osteotomy may be likened to subcutaneous tenotomy. (*a*) In its simplicity, certainty, and freedom from complications; (*b*) In the advisability of correction of the deformity at the time of operation, in the facility with which union occurs and gapes are filled up, in the importance of careful and intelligent postoperative treatment, and in the permissibility of locomotion before firm union has occurred, provided the parts are perfectly controlled by splints. Each is indicated when the structures involved can not be permanently corrected by stretching in a reasonable time, and both mark a distinct advance in the treatment of certain deformities and are worthy of wider recognition.

The Successful Treatment of Gonorrhœa and All Inflammatory Diseases of the Urethra by Packing with an Antiseptic Oil Dressing.—S. T. Rucker carries out the usual preliminary irrigation, and then passes the packing tube (a special variety of which is figured) about four inches in anterior gonorrhœa and back to the neck of the bladder in posterior gonorrhœa and prostatic troubles. The urethra is then lightly packed with one inch continuous gauze strips, or better, a loosely-spun cotton cord saturated in 95 grains of iodoform rubbed up with three and one-half ounces of castor oil, to which mixture half an ounce of Peruvian balsam is added. This makes practically an odorless mixture—or we may employ ichthyol and resorcin in the oil and balsam (formula given). The instrument is gradually withdrawn as the dressing is pushed through, and when it emerges from the meatus the cord dressing is clipped with scissors, leaving about one-eighth inch of the cord outside of the meatus, which can be taken between the fingers when the cord is to be removed. A small piece of cotton is placed over the head of the penis and treatment is complete. The patient is now instructed to go as long as he possibly can before urinating, when the cord is slowly removed. The average patient will go from five to eight hours before urinating without much discomfort. The patient can wear the packing all night. It is to be renewed daily, at night, until discharge ceases. During the day, the author employs various injections in much the usual way. So much detail of treatment is mentioned over and above the packing that it is difficult to accurately determine just what the effect of the latter really is and how much it facilitates recovery.

Medical News, October 11, 1902.

An Instance of Accidental Vaccination.—Geo. W. Kosmak reports an interesting case of this kind. A mother was vaccinated, and the pock ran a normal course and was not protected by any dressing. Her little girl of fifteen months slept in the bed with her. About two weeks after the mother's vaccination a small red spot appeared on the baby's cheek, and ran the normal course. There was a slight infection, and the neighboring lymphatic glands were somewhat enlarged and tender. There were no signs of any skin eruption, and the child, undoubtedly, inoculated itself through the healthy skin, probably by scratching. An unsightly scar will be left on the child's cheek.

How Much Do We Positively Know about Tuberculosis? A Plea for the Tuberculous.—F. C. McGahey declares that we are ignorant as to the cause that makes an individual susceptible to tuberculosis. Syphilis and gonorrhœa are more infectious than tuberculosis, as they are contracted by those having no especial susceptibility. The writer relates various instances in which individuals have been exposed to tuberculosis, but have not contracted the disease. He states that these facts undoubtedly prove that it takes more than an atmosphere loaded with bacilli to produce the disease. As to whether the tendency to tuberculosis is inherited, the history of the Indians answers both "no" and "yes." The writer does not combat the use of any antiseptic measure for the prevention of the disease, but he fears that our precautions often accomplish little or nothing at all. He believes that although ordinances against spitting are very good, a better one would be that exacting a heavy fine from women wearing skirts which are not at least two inches from the ground. This would be a protection against other infections as well. Although separate cars for consumptives may be desirable, still more so are leather coverings instead of plush for seats, and linoleum for the entire floor. The car could then be cleansed after each trip with an antiseptic solution. Plush and carpets ought not to be in any public building, whether church or theater. Those who seem susceptible to tuberculosis should shun all crowded, ill-ventilated, carpeted, and soft-cushioned places. Our public schools demand many antiseptic measures, and here practical instruction in antiseptics could be given.

The Etiology of Shock.—H. H. Stoner states that it is clear that the phenomena of shock are manifested through the agency of the sympathetic nervous system. A direct relation exists between shock and the activities of the sympathetic nervous system. Shock may result either directly from injury to the sympathetic system, or indirectly as a result of disturbed metabolism. Shock, as usually seen, presents itself under one of two clinical forms. It may be attended with great excitement or with utter prostration. Blows over the sympathetic plexuses or upon organs richly supplied with sympathetic nerves produce a condition of shock identical with that of incised or lacerated injuries. This is due to the injury to the sympathetic nerves. Abdominal operations are especially productive of shock. This is undoubtedly due to the chilling to which the sympathetic nerves of the viscera are subjected. Hemorrhage is a fruitful cause of shock. In this case the stimulus which induces the shock originates directly in the bodily tissues. When the blood supply is suddenly withdrawn, retrograde metamorphosis immediately ensues in all parts of the body, and the stimulus—the demand of the starving tissues—incident thereto is sufficient to set up the sympathetic disturbances. Prolonged anæsthesia is often alone sufficient to induce a profound degree of shock. The different effects of shock are explained on the assumption that these symptoms are produced by the effects made upon the cerebrospinal nervous system. In the cases of excitement the metabolic stimulus is such as to affect the psychical apparatus, so that an emotional state is produced. In the cases of torpidity the metabolic activities are retrograded, so as to nearly detroy the tonicity of the cerebrospinal system. The flush of shame and the pallor of fear are produced through the agency of the sympathetic system. The same agent that produces the flush of shame is the same that causes the flush which attends the state of shock. No doubt both are due to an impression acting upon the vasomotor system which dilates the walls of the capillary blood vessels. Shock, then, and the activities of the sympathetic nervous system are directly related.

New York Medical Journal, October 11, 1902

The Constitutional State vs. Catarrhal Deafness.—S. F. Snow calls attention to the necessity, in addition to local treatment of the ear and nose, of looking after the functions of the skin, liver, stomach, and bowels. Unless we do this, local treatment will fall short of its possibilities. Regular bathing, friction of the skin, vigorous exercise—all must be insisted upon. Dyspeptic or intestinal disturbances, as well as uric acid and intestinal troubles, produce an irritability of the mucosa lining the head passages quite sufficient to call for connection before we can expect the Eustachian tubes to remain patent. It goes without saying that necessary operative work within the nose must be done, and done thoroughly, for no one with a projecting nasal spur or pressing middle or prolapsed lower turbinate has proved to me that the reason why many attempts to relieve chronic catarrhal deafness result in failure is principally because constitutional factors have not been appreciated.

The Silent Forms of Epilepsy. According to W. P. Spratling, such attacks come from frontal lobe disturbances. They may be of two kinds: (1) The psychomotor epileptic equivalent and the psychical attack pure and simple, the former being more violent, more commotional in character, and having a general motor disturbance, but no regular convulsion; the latter (often unrecognized) always quiet and unobtrusive and free from motor disturbance of any kind, but surely destructive, in the end, of the mental faculties. These patients are generally remote. They have a feeling that something is wrong; they are apprehensive, restless, nervous, given to sudden impulses, solicitous, unable to act or think logically in a well-balanced and connected way, and, above all they have a bad memory, because new impressions are so often destroyed by swiftly changing conditions in the brain that lead to disorganization of the brain cells that hold the function of memory. It is difficult for them to grasp things pointedly and clearly, and at times, when the seizure is present, although they may seem to be in a normal state, their perceptive senses are like camera plates that have been exposed—the recording surface is clouded over, dead to new impressions.

The Indications and Limits for Operation by the Vaginal Route.—According to C. C. Thienhaus, the advantages of this method are as follows: In operating by the vaginal route there is less danger of infection and shock, drainage in suitable cases is established through the lowest possible part of the body, there is no visible scar or possibility of ventral hernia, the convalescence after operation is usually smoother, simpler and shorter, in vaginal shortening of the round ligaments of vaginal suspension of the uterus, for instance, only from eight to twelve days. For cases of permanent abscess lying in the posterior cul-de-sac and for cases of parometritic and paravesical abscesses with and without pyosalpinx and pyovarium, the vaginal route is the method *par excellence*. Not all cases of simple pyosalpinx are attainable by this route, nor is a permanent cure effected by mere vaginal *incision and drainage* through the vault. In case of unilateral involvement of the appendages while those on the other side are perfectly normal, the author prefers the abdominal route. Extrauterine pregnancy with hæmatoma may call for both incisions, while, with the latter alone, the vaginal route will usually suffice. In cases of retrodisplacements, unless contraindications exist in the shape of extensive adhesions and serious disease of the adnexa, the vaginal route is to be preferred. So, also, it is preferable in prolapse of the uterus with or without cystocele. For surgery by the vaginal route two requirements are necessary: (1) Greatest care in diagnosis and judgment in the selection of cases. (2) Absolute familiarity, as well theoretically as practically, with all *abdominal* operative procedures on the female sexual and adjacent organs, because the necessity may arise (though very seldom in the hands of experts) of resorting to the combined vaginal and abdominal methods of operation.

American Medicine, October 11, 1902.

Brewers' Yeast in Therapeutics.—Julius Ullman states that brewers' yeast, because of its ferments, nuclein, nucleinic acid, and phagocytic action, is a remedy of value in therapeutics; its use is not confined to any one disease, but wherever an increased resistance of the organism is required. It has proved itself of value in furunculosis, carbuncles, diabetes, tuberculosis, bronchitis, bronchopneumonia, enteroptosis, habitual constipation, cancer, and other affections. Used in cases of advanced tuberculosis, an improvement in symptoms, indicative of secondary pyogenic infection, was noted. The therapy with fresh brewers' yeast is applicable only in such places where it can be obtained fresh from a brewer, and it must be obtained daily.

An Additional Case of Typhoid Spondylitis.—Albert H. Freiberg reports this case. The patient was a boy of fifteen years, admitted to the hospital on February 18, 1901, with typhoid fever. The illness had begun a few days before. On March 29 he was allowed to be on his feet, but he complained of pain in the lumbar region, which continued after he resumed his recumbency. On April [illegible] he was put to bed again, because the pain in his back had grown much worse and more constant. It was most severe at night, the spine tender on pressure, but there was no elevation of temperature. The pain grew worse till morphia, in ordinary dose, was only slightly effectual in quieting the nocturnal pain. The writer made an examination of the patient, and noted a decided projection backward of spinous processes involving the eleventh and twelfth dorsal and the first and second lumbar vertebræ, at the height of which the greatest tenderness was found. There was a diffuse swelling, extending both laterally and vertically beyond its limit, also sensitive to pressure. This required fairly deep pressure to make it evident. The back muscles were rigidly contracted. The tendon reflexes were somewhat exaggerated at the knees, and there was slight ankle clonus. No impairment of sensation was noted. A plaster bed was made for the patient, with the spine in a hyperextended position. There was great relief. On May 8 a plaster jacket was substituted for the plaster bed, and the patient was allowed to go about. He was discharged from the hospital on May 23. There was still considerable stiffness of the spine, the bony deformity was unchanged, but the swelling of the soft parts had entirely disappeared. In February, 1902, the deformity at the lumbodorsal junction was about the same. The spine was freely mobile, except in this region. He has had no symptoms of any kind since his discharge from the hospital, and, though working steadily, he is the picture of health. The writer believes that an inflammatory lesion, with circumloss of bone, had existed.

The Pathology of Chronic Specific Dysentery of Tropical Origin.—Charles F. Craig describes acute specific dysentery, in contradistinction to the more common form occurring in the Philippine Islands, which is due to the amœba, and is known as amœbic dysentery. This report is based up on the autopsy findings in 103 cases. There are three classes of these cases: follicular, diphtheric, and gangrenous. Undoubtedly all of these different pathologic lesions belong to one process, beginning as follicular and ending in the gangrenous form. However, there may still be separated these three distinct classes, from a pathologic standpoint, each having its own peculiar lesions, and each to be studied separately. The writer then considers the subject as follows: First, the character of the dysenteric stools. Much can be learned as to the type of dysentery present by a careful examination of the fæces. The fæces of the follicular stage vary greatly in number, usually from three to twenty during the twenty-four hours. As a rule, they are of semi-fluid consistence, and show little blood. They are not very offensive. During quiescent periods of the disease, the stools are often formed. Numerous pus cells are found in a majority of the cases. A large majority show numbers of mucous corpuscles imbedded in stringy mucous. The epithelial cells are abundant. There are fragments of undigested food. The bacterial flora is varied, and extensive. In none of these cases was the amœba of dysentery observed. The stools of the diphtheric stage are very different. They are made up of a serous body, in which are suspended shreds, strings, and pieces of pseudomembrane, cells, and small portions of intestinal mucous membrane. There is a mixture of blood, pus, mucous, and undigested particles of food. The color varies from slate to red. The odor is horribly offensive. Immense numbers of bacteria are present. No amœbæ of dysentery were found. In the gangrenous stage the stools are a thin, slimy syrup, of a slate-brown or black color, in which are pieces of necrosed mucous membrane, undigested food, and greenish pus. The odor is very offensive. There are many blood and pus corpuscles, and bacteria. This stage is an intense diphtheric infection. The next point considered is the gross and microscopic pathology of the three stages. In the follicular stage the intestines are, as a rule, dilated with gas. The external color of the large intestines is generally a dull gray, or slate; that of the small intestine varies from almost white to a bright pink. The jejunum and ileum are excessively thin. The region around the ileocæcal valve is the part of the large intestine most often involved. Microscopically, the most characteristic lesions are found in the solitary follicles. Many leucocytes are gathered round the follicles. The process consists essentially in a necrosis and ulceration of the solitary glands, or follicles, of the large intestine, with an extension of the process to the mucous and submucous coats, and sometimes to the muscular coat. Atrophy and loss of function of the tissues affected finally occur. In the diphtheric stage the lesions are divided into involvement of the mucosa, without any diphtheric deposit, involvement of the mucosa and a deposit of diphtheric exudate upon the surface of the membrane, involvement of the mucosa, submucosa, and even the muscular coat, with coincident diphtheric deposits upon the surface of the mucous membrane. The gangrenous stage may, perhaps, be regarded as a very intense type of the diphtheric stage, or the further development of that stage. The writer has not been able to obtain cultures of Shiga's bacillus in most of the cases coming to autopsy, but he has used pure cultures of this bacillus in testing the action of the blood-serum of these cases, and in all has obtained a marked agglutination. This reaction has not been present in the cases of amœbic dysentery, according to his work; thus he believes these cases to be the chronic form of the acute specific dysentery prevalent in the Philippines. The term "tropical dysentery," as denoting dysentery due to infection with the amœba, is unwarranted in the sense that amœbic dysentery is the only type occurring in the tropics. All of these cases originated in the tropics, and are as really tropical as amœbic dysentery.

Philadelphia Medical Journal, October 11, 1902.

The Infraspinatus Reflex; a Question of Priority.—William Pickett calls attention to the German contribution by Professor Steiner of Cologne in the *Neurologisches Centralblatt*, September 16, 1902, the title being "The Infraspinatus Reflex: a Hitherto Unknown Reflex of the Upper Extremity of Man." This reflex was described by the writer in a paper on the scapulohumeral reflex of Bechterew, based upon work done at the suggestion of Dr. Dercum, read before the Neurological Society nearly two years ago, and published in the *Journal of Nervous and Mental Disease* May, 1901. This reflex, under consideration with the pectoral reflex, and another mentioned in the writer's paper, were all considered at the time of discussion, as modifications of von Bechterew's reflex, since the motion of the arm is similar in all, and the spinal center of each is in the same segments of the cord, with the possible exception of Mills' "pectoral" reflex.

Severe Burn of the Eye and Face by Nitrite of Amyl, with Loss of the Eye.—Edward A. Shumway reports this unusual case. The patient was accustomed to use nitrite of amyl as soon as he experienced an aura, which was the forerunner to convulsions to which he was subject. On one occasion the convulsion came too quickly, and he threw a portion of the contents of the bottle of amyl nitrite into his eye, accidentally. As a result, there was a deep burn of the cornea and conjunctiva, which extended to the skin of the right side of the face. Despite prompt treatment, the cornea sloughed and the eye was destroyed. The explanation of this effect of the drug was finally made: The patient had been supplied with nitrite of amyl which, by repeated exposure to light and air, had decomposed, and at the time of the accident, probably consisted largely of a mixture of nitric and nitrous acids, to which the severe burn was due. He gives the following suggestions as lessons to be learned from this case: (1) Nitrite of amyl should be supplied to patients, for inhalation, only in the form of glass pearls; (2) When in quantity it should be kept in small, well-sealed, glass-stoppered bottles, in a cool, dark place; (3) A specimen which has been used a number of times should be tested very carefully, and if, on examination, it is found to have a decidedly acid reaction, it should be at once discarded.

Gastroptosis: a Method of Suspending the Stomach in a Hammock Made of the Great Omentum. R. C. Coffey describes two of these cases. The first patient was a woman, aged forty-four years. Examination showed the abdomen so tender that a thorough examination could not be made, and a digital examination per vaginam revealed a retroflexed uterus, with an adherent ovary back, and to the left side of it. A blood examination showed 20 per cent. diminution in hæmoglobin. A satisfactory diagnosis was possible only under an anæsthetic, or more probably an exploratory incision would be necessary. This proved to be true, and when the incision was made no small intestines were visible. The entire pelvic cavity was tented over by the omentum, which had become adherent by strong adhesions to the peritoneum lining the anterior brim of the pelvis. The lesser curvature of the stomach was almost two inches below the umbilicus. The appendix and cæcum were included in the adhesions. The stomach was fixed and could not be brought out of the wound until the omental adhesions had been separated from the pelvic peritoneum. The stomach was then pushed up out of the way. The ovary, which was adherent in the cul-de-sac, was removed, the uterus stitched to the abdominal wall, and the appendix removed. The problem then arose how it would be possible to protect the stomach from again being drawn into the pelvis by a readhesion of the omentum, for the tendency of the stomach was to come down into the wound, even though the adhesions had been broken up and the patient was still in the recumbent posture. Finally, the omentum was stitched to the abdominal peritoneum, about an inch above the umbilicus, by passing chromicized catgut sutures through the omentum about an inch below its attachment to the stomach. Three sutures were placed in this case about an inch apart, the line of sutures running transversely. In this way the stomach was out of the way and firmly in place. The abdomen was closed and the patient put to bed, with the lower extremities elevated. She was kept in the recumbent position, with her head lowered, for nearly five weeks, feeling almost entirely well. She went home during the eighth week. A bandage was fitted, and the patient was instructed to lie down an hour after each meal, and exercise very cautiously. Within a few weeks she could eat anything she desired without distress, and she felt that her condition was absolutely cured. She is now doing her own housework.

The Lancet, October 4, 1902.

Notes on Three Cases of Inoperable Cancer of the Breast Treated by Removal of the Ovaries.—The histories of the cases related by D'Arcy Power may be summarized as follows: Case 1.—Single woman of fifty-two years with ascites and fungating breast; axillary and supraclavicular glands so enlarged and fixed that removal was impossible; removal of breast and ovaries; general studding of intestines with cancerous nodules; patient lived six months. Case 2.—Widow of forty-two years; cancer involved right breast, axillary glands, and infraclavicular fossa; ovaries removed and found cystic and cancerous. A few months later the mammary region was much less swollen and general health was greatly improved. Case 3.—Woman of fifty-five years with cancer of left breast, removal of ovaries, which were free from disease; mammary region became much softer, but later hardened up again; in other words, the removal of the ovaries in the patient, who had not passed the menopause, was followed by an arrest and apparently a retrocession of the cancerous disease, while in the other two the operation was not followed by any benefit.

Myelopathic Albumosuria.—By this term T. R. Bradshaw designates a group of cases characterized by albumose in the urine and some affection of the bone marrow. The cause is unknown. The changes in the skeleton consist in the invasion of certain bones by a soft mass of new growth, the osseous tissue proper undergoing absorption. The new growth is red, soft, and gelatinous, looking like red marrow. It shows chiefly round cells with little or no intercellular substance. In structure and course of development it resembles sarcoma. The urine contains a proteid closely resembling albumin, but differing from albumin in certain particulars, of which the following are the most obvious: (1) It coagulates at a remarkably low temperature, viz., 58° C., (2) the coagulum is, to a great extent, dissolved at the boiling point and reappears on cooling; (3) the coagulum which forms on treatment with cold nitric acid also dissolves on boiling and returns on cooling; and (4) it is readily coagulated by hydrochloric acid. The symptoms are those of progressive asthenia accompanied by pains in the back and side suggesting rheumatism or neuralgia. The pains shift their position and vary in intensity. Swellings are found on the bones—or they are yielding to manipulation, and the *x*-ray may show an interruption of continuity. The prognosis is always bad. Concerning the peculiar substance, in the urine, we only know that it resembles albumin. As regards the mode of formation of the substance, three different views have been put forward: (1) The old view was that it is derived directly from the proteid constituents of the food, which, for some reason, fail to undergo the normal metabolism. This view ignores the fact which lies at the root of the whole problem, viz., the association of the albumose with disease of the bones and marrow. (2) Another view is that the albumose is produced by some abnormal metabolism taking place in connection with the new growths in the bones. How this could happen is at present a matter of pure conjecture, but it might conceivably take place through the action of a ferment. (3) Finally, it has been suggested recently that the formation of the albumose takes place as the result of the loss of some function of the bone marrow, owing to the destruction of the latter. Bradshaw believes that the second of the theories best explains the phenomena of the disease.

The Medical Treatment of Appendicitis, with Notes of Three Illustrative Cases.—The histories of the cases are given by J. Burnet. In addition to the general and careful nursing, reliance was placed on fomentations keeping the bowels open by cascara, belladonna, etc.; stimulants, if necessary, and the avoidance of opium. All recovered, but their subsequent history is not stated. As to when the surgeon should be called in, the author thinks that such aid should be summoned only when, in spite of the careful carrying-out of the treatment already indicated, the patient's condition is evidently becoming worse. In dealing with appendicitis we are apt to expect too much in the way of improvement from day to day. During the satisfactory progress of many of these cases the improvement is sometimes hardly perceptible, but if it is observed after a careful estimation of every factor involved, then we are warranted in persevering with our medical treatment rather than in summoning a surgeon to our aid. He has no hesitation in saying that many cases of appendicitis are operated on which would have made a good and even a speedy recovery under medical treatment pure and simple. Surgeons urge that there is less risk in operating while the patient's strength has not yet been exhausted than in letting the disease run its course. All this is, to a certain extent, true, but we can do a great deal to carry the patient through his illness and to prevent complications setting in by careful attention and by intelligent medical supervision. Treatment during convalescence, too, is of great importance. When the temperature and pulse have remained normal for about a week the patient may be gently lifted on to a couch for a few hours each day. At the end of a month or six weeks he should be sent to some bracing, but quiet country place. During this period the greatest care in dieting is necessary, as is also the avoidance of constipation. Nothing that is in the least likely to upset the digestive organs should be taken, and the bowels must be made to act once a day. The convalescent should be warmly clad, woollen underclothing being most essential, and be careful to guard against chills.

British Medical Journal, October 4, 1902.

Discussion on the Prevention of Scurvy.—Alexander Turnbull declares that lime juice must only be considered as the most valuable adjuvant in the prevention of scurvy, and not as an absolute and complete substitute in itself for a proper antiscorbutic diet. The writer has carefully studied this subject, and concludes that the presence of some toxic material in the food is the exciting cause of scurvy, afloat and ashore, and that lemon or lime juice has been erroneously accepted as a certain preventive to the neglect of requisite precautions in provisioning. The true antiscorbutic is purity of food.

The Treatment of Abdominal Wounds in War.—Charles Roberts concludes that: (1) As a rule, the conditions in a field hospital are not suitable for performing laparotomy. Moreover, many patients with penetrating abdominal wounds recover without operation, and in the majority of those who die the nature of the injury is such that death must result whatever be the conditions of operation, and an exploratory laparotomy may add a fresh danger to the patient. (2) When occasions arise in which the conditions of operation approximate to those in civil practise, laparotomy should be undertaken for increasing intraperitoneal hemorrhage endangering life, and when there is evidence that perforation of the stomach or bowel probably exists, provided that the patient is seen early enough.

Consumption in the Navy.—Gerald Sichel says it may be confidently assumed that in the navy, as elsewhere, the lungs are *par excellence* the favorite sites both for infection of the individual patient and for propagation of the disease to others. Tuberculosis costs the English navy £20,000 per annum. The question of ventilation is of the first importance so far as the cure of consumption is concerned. The remedy for this disease is in prevention rather than in cure; that is, in prompt diagnosis. Careful microscopical examination probably affords the surest and earliest method of making a reliable diagnosis. On the other hand, exceptionally, the bacillus can only be demonstrated after prolonged and frequent search in cases in which physical signs point to advanced disease. Once tubercle bacilli have been demonstrated, the only proper course is to at once invalid the man out of the service. The writer concludes by emphasizing two important practical points: (1) We should consider it our earnest duty, more particularly on board ship, to carry out the needful simple examination of sputum systematically. (2) Every medical man, whenever he gets the opportunity, should urge the necessity for compulsory notification of tuberculosis throughout the country.

Deutsche medicinische Wochenschrift, September 18, 1902.

Nutrition During Hot Weather and in Warm Climates.—Felix Hirschfeld says that during hot weather and in warm climates meat should be very largely restricted in the diet. Voits' idea, which has been adopted by most physiologists, that 118 grams of albumin is the minimum amount required by the body for its proper nutrition, is entirely erroneous. The author, in a series of experiments conducted upon himself, has shown that this amount may even be reduced to 39 grams during hot weather, without in the least interfering with proper nutrition, and with much benefit to the physiological processes generally. The deficit is to be made up by an increased amount of fats and carbohydrates. Such a marked restriction in meat is not, however, to be advised for all persons during hot weather, but only in those who experience a loss of appetite while eating the usual amount of meat during such a period. Much observation has shown that under such circumstances a marked reduction in the meat diet leads to an increase of appetite and an improvement in the general condition.

Practical Results of the Forensic Serum-Diagnosis of Blood.—Uhlenbuth has endeavored to demonstrate the practical value of his method of serum-diagnosis of blood, by obtaining from legal sources various specimens of blood, the sources of which were unknown to him. These specimens were tested with known specific sera and the diagnosis of the origin of the bloods thus made. In all, twenty-one specimens were examined, and in every instance the diagnosis of the origin made by Uhlenhuth corresponded with the known origin as obtained from the legal authorities. Hitherto all of the examinations which have been made along these lines have been so conducted that the examiner himself knew the source of the blood before he made the examination, so that it might be thought possible that his judgment might be influenced thereby. The examinations here reported are void of this objection, and fully demonstrate the practical legal value of the method. It must not be supposed, however, that this method, valuable as it is, does away with the chemical or spectroscopic examination of fluids or spots which are submitted for diagnosis. First of all, it must be shown that the specimens are blood. Only the chemical or spectroscopic examination can establish this. The specific sera give positive reactions, not only with the albumin of the blood, but also with all other albumins from the animal against which they are specific. Thus a serum specific for human blood gives a positive reaction, not only with human blood, but also with human seminal fluid, human urine containing albumin, and human hydrocele or ascitic fluid. The chemical or spectroscopic examination should, therefore, always precede that which is to be made by means of a specific serum. For the reliable execution of this method, several precautions are necessary: (1) The specific sera used must be of very high power; (2) In all cases such sera before use must be tested with the blood against which they are specific, and their activity thus demonstrated; (3) Opalescent sera should never be used, as confusing reactions are frequently given thereby; (4) In carrying out the examination, controls should always be made; (5) No reliance should be placed in the results unless the examination has been conducted by one who has had extended experience along these lines.

Berliner klinische Wochenschrift, September 22, 1902.

Multiple Hereditary Exostoses.—Jungmann reports three cases—a father, son, and daughter. The father was thirty-nine years of age, and the son and daughter nine and six years respectively. In none of the cases were the tumors congenital. In all they were more or less symmetrical in their arrangement. The son showed the greatest number of tumors. They had first made their appearance when the patient was about three years of age. In all of the patients the tumors were painless and occasioned no inconvenience. Similarly, as in other reported cases, certain of the tumors, which had been previously present, had isappeared. Considerable discussion has taken place concerning the relations existing between these tumors and rickets. Of these three patients only one—the boy—showed any symptoms of rickets. Even here the only suspicious sign was the peculiar formation of the chest, which somewhat reminded one of that so frequently met with in rickety children. Certain authors attach importance to the shortening of the bones, which possess the greatest number of tumors. While this may, as a rule, hold true, it is evident from these cases that such is not always present. In all of the cases many of the bones which contained no tumors were much shorter, proportionately, than normal, while some of the bones which contained many were of the usual length.

Transference of Human Tuberculosis to Cattle.—Johannes Fibiger and C. O. Jensen report the results of observations with respect to this subject. The patients chosen for examination were those in which primary intestinal tuberculous infection was proven on the ground of the clinical symptoms and post-mortem appearances or in which, for the same reasons, such was extremely probable. In all, five patients were examined. Of these, two were adults and three were children. The two adults were in all probability cases of primary intestinal infection, although that such was the case could not be absolutely demonstrated. A calf was inoculated intrapleurally with portions of the tuberculous mesenteric glands of the first case. The animal never developed any symptoms of tuberculosis, and remained in good condition. It was killed in about six months from the time of inoculation. At the site of inoculation on the pleura, there were found two miliary tubercles. This is to be regarded as a negative result. Another calf was inoculated intraperitoneally with portions of the tuberculous spleen of a guinea-pig which had been subcutaneously inoculated with portions of the tuberculous mesenteric glands from the second case. This calf developed no symptoms of tuberculosis, and was killed in about three months. On the peritoneum there were found numerous recent, typical tuberculous deposits. The lungs, liver, spleen, and kidneys were normal. The result, therefore, here was positive, although it is evident that the virulence of the bacilli inoculated was very slight. In the case of the first child, a calf was inoculated intraperitoneally with material obtained in a similar manner to that obtained in the case of the second adult above noted. About three weeks later the animal showed a slight elevation of temperature, which lasted several weeks. After three months it was killed. Numerous typical tuberculous lesions were found on the peritoneum and in the spleen and liver. Portions of the tuberculous mesenteric glands of the second child were inoculated subcutaneously into the side of the neck of another calf. An ulcer developed at the site of inoculation, and the neighboring lymphatic glands became swollen. The general condition of the animal remained good. It was killed after four months. The right lung, liver, spleen, and kidneys showed numerous typical tuberculous lesions. The mode of procedure in the case of the third child was similar to that carried out in the previous case, except that two calves, each about ten days old, were inoculated. One of these calves died in about nineteen days from a putrid embolic lung lesion. The ulcer at the site of inoculation contained numerous tuberculous bacilli. The other calf died in twenty-one days of a septic pleuropneumonia. The ulcer at the site of inoculation contained numerous tuberculous bacilli. Portions of the cervical glands of the second calf were inoculated subcutaneously into the right side of the neck of a third calf. This calf developed a temperature and emaciated rapidly. It was killed in about two months. Numerous tubercular lesions were found in the lungs, liver, spleen and kidneys. A cow, ten years old, was similarly inoculated with glandular material from the first calf. This animal developed a temperature. The ulcer at the site of inoculation contained numerous tuberculous bacilli. It was killed in three months, and typical tuberculous lesions were found in the lungs, liver, spleen, and kidneys. As the result of this work, it is certain that calves are susceptible to infection with tuberculous bacilli obtained from human cases of primary intestinal tuberculosis, and it is extremely probable that the bacilli causing these lesions in the human being are frequently of bovine origin. Koch's view that tuberculous bacilli of bovine origin are harmless for man is, therefore, erroneous.

Munchener medicinische Wochenschrift, September 23, 1902.

Habitual Use of Large Doses of Digitalis. C. Schubert reports the instance of a patient who developed a mitral insufficiency as the result of a rheumatic attack, and who was ordered to take digitalis for the relief of the symptoms resulting from the cardiac non-compensation. This drug was given in the form of the infusion, of which two to three teaspoonfuls were taken three times a day. This dose was gradually increased until from eight to twelve ounces were consumed weekly. This was continued for about six years, when death occurred. During this time compensation was fairly well maintained. A careful estimation showed that during this period the patient had taken at least 500 to 600 grams of digitalis.

Traumatic Nephritis.—H. Curschmann, Jr., reports a case which he regards as a traumatic nephritis, and, in particular, belonging to that variety of this condition described by Stern in which albuminuria and cylindruria are the only symptoms present. Albumin was first detected in the urine about nine months after the reception of the injury, which consisted essentially of a crushing and contusion of the back. At several subsequent examinations no albumin was found. A recurrence, however, occurred about six months after the initial detection. At both of the positive examinations the amount of albumin present was very small. The case first came under the observation of the author about eighteen months after the injury. At this time the urine contained albumin and hyaline and granular casts in small amount. Several subsequent examinations showed a similar find. Absolutely no other symptoms of a nephritis were present. Especially should it be noted that the heart and circulatory apparatus were entirely normal. The diagnosis of a traumatic nephritis is based upon the history of the patient, who negatived the previous occurrence of all diseases, the sequel of which might be a nephritis, and the fact that following an injury in the region of the kidneys there developed an albuminuria and cylindruria which was unaccompanied by any other signs of a nephritis.

Pathogenesis of Typhoid Fever.—H. Schottmüller, having previously published his results with respect to the isolation of typhoid bacilli from the blood of typhoid patients, now summarizes the same with regard to their value in the diagnosis, prognosis, and a clearer understanding of the pathogenesis of this disease. The fact that such isolation tests were successful in 80 per cent. of the cases examined shows that their value as a means of diagnosis is second to none. Especially is this apparent when it is stated that many times the bacilli were so isolated from the second to the fifth day of the disease before the Widal reaction was positive. A critical review of the results also shows that the number of bacilli isolated, and the intensity of their cultural growth, corresponds closely with the intensity of the clinical symptoms present, so that, as a rule, severe and fatal cases show the largest number of bacilli and the most rapid cultural growth. In all instances, as the case progresses toward recovery, the number of bacilli lessen and their cultural growth becomes weakened. In no instance were typhoid bacilli obtained from the blood after the temperature had reached normal. In many instances a relapse was preceded by the appearance of bacilli in the blood. Sex does not seem to exert any influence upon the presence or number of bacilli present in the blood. As a rule, children gave more negative results, and a fewer number of bacilli in positive cases, than did adults. From all of these facts it is certain that typhoid fever is to be regarded as a bacteriæmia, the symptoms being directly due to the presence of typhoid bacilli in the blood. It is not as yet entirely clear whether or no the bacilli multiply directly in the blood. It is very probable, however, that such is the case in all instances in which anti-bodies are not present in the blood in sufficient amount to prevent such multiplication. The lymphatic structures throughout the body are locations to which the typhoid bacilli are predisposed entirely, similarly as in other diseases certain microorganisms find favorite locations. That in the lymphatic structures typhoid bacilli multiply with greater rapidity than in the blood is certain. It is probable that the typhoid bacilli gain entrance into the system through some lesion of the intestinal tract, and are carried by the lymphatic vessels into the general circulation whence they are transmitted to the lymphatic structures generally, in which they find especially favorable conditions for growth. According to this view the lymphatic lesions in this disease are to be regarded as metastases, and not as primary lesions. It has now been definitely shown that in many instances typhoid bacilli are to be found in the lymphatic structures long after they have disappeared from the blood and the clinical symptoms have subsided. Relapses are due to the readmission of such bacilli into the general circulation.

French and Italian Journals.

A Case of Thomsen's Disease Due to Cerebral Lesion. Giuseppe Rizzuti reports the case of a soldier suffering from this disease, characterized by disorders of mobility and by spastic rigidity of the muscles. The attacks were not always of equal severity, and not always present. At the age of twelve years, the patient's skull was fractured by a falling implement, and after healing was wounded again in the same place by a blow. Examination showed a longitudinal depression along the sagittal suture for about four centimeters length on the top of the skull. Careful research excluded all other causes of the disease, and the author concludes that the affection was due to traumatism.—*Giornale Medico del Regi Esercito*, August 31, 1902.

The Influence of the Bile in the Resisting Powers of the Red Corpuscles.—G. Viola and B. Jarugi have found, as a result of their experimental researches (1) That resistance is not always, but is usually, increased in both acute and chronic icterus. (2) The increase of resistance affects all three forms (minimum, medium, and maximum resistance) only occasionally, leaving out the minimum form which may even be decreased while the other two are increased. (3) There are some cases of icterus in which there is no increase in any of the resistances, but diminution of the minimum resistance. (4) Finally, a case has been seen in which there was increased medium resistance alone. The matter is seen to be anything but simple.—*La Riforma Medica*, September 16 and 17, 1902.

Primary Medullary Carcinoma of the Lung.—A. Pitini and F. Mercadante reports a case in which a diagnosis was made of some intrathoracic tumor. At autopsy the left lung was found to contain many scattered nodules, the size of a walnut. The upper lobe of the right lung was composed of one solid mass, while the middle and lower lobe were filled with nodules. Histological examination showed that the mars and the nodules were typical epithelioma. Nothing during life had indicated the existence of these nodules; there was no characteristic sputum, no hæmatopsys, no hemorrhagic effusion into the pleura, not even cachexia. There had been cough and dyspnœa, and abolition of vocal fremitus on the right side, with resistance in the right supra- and subclavicular regions. Death was preceded by fever, purulent expectoration, and pleural and pericardial effusion.—*La Riforma Medica*, September 10, 1902.

Contribution to the Study of Sialorrhœa in General Paralysis.—E. Marandon de Montyel gives various conclusions on this subject, among which are the following: Salivation was twice as often observed during the crises of agitation as in the periods of calm. It is the syphilitic paralytics who have furnished the largest proportion of salivation and of an excessive degree. It is in the early general paralysis, from twenty-five to thirty years, and in the late, from fifty to sixty years, that salivation has most often been determined, still it is the first that has given the greatest number of cases of moderate degrees of it. The seasons have no sensible influence. Salivation was determined six times more often with excessive motor troubles than in those of light degrees, but the degree of intensity was in inverse rate to the degree of frequency. Salivation has never manifested itself only once in the patients studied, it has always continued, and has never presented the intermittent type. This trouble more often lasted about five months, though its duration varied. Salivation may begin in a moderate degree, pass on to an excessive stage, and then disappear suddenly, or it may begin in an excessive degree, and finish in a moderate one.—*Gazette des Hôpitaux*, October 2, 1902.

The Impetigo of Bockhart and Its Treatment.—Balzer states that this affection in acute cases in general disappears soon after the simple application of a calomel ointment 1-100 or 1-50 in strength. Treatment may be begun by applying moist compresses, wet in boiled water, or in sublimate 1-5,000, before applying the ointment, or white precipitate. If the eruption has been irritated by such agents as oil of cade, iodine, etc., the causes of irritation should first be suppressed which have facilitated the inoculation of the staphylococcus. In certain cases, lavage with a phenic solution 1-200 is efficacious. The Germans recommend the following method: After having taken off the crusts, the places are disinfected with a small brush dipped in a strong solution of 10 per cent. resorcin in alcohol; a pomade of resorcin from 3 to 5 per cent. is then applied. The writer has also applied with success a solution of methylene blue, 1-250, advised by Brocq. The patient is recommended to wash with a decoction of panama wood and neutral soaps, in which may be incorporated a small quantity of resorcin. Tar soap should be avoided and all other irritating substances. The general condition should be looked after in the chronic forms, as it nearly always needs more or less attention. Tonics should be given as the phosphate of soda, or lime, and phosphoric acid, iron, and arsenic.—*Le Bulletin Médical*, October 4, 1902.

The Heart in Diphtheria.—According to Joseph Girard, the best prophylactic treatment of cardiac paralysis consists in the early employment of antitoxic serum. It is best to keep the patients in bed until convalescence is clearly established. The pulse should be watched very carefully, the appearance of even a slight weakness of the pulse or of rhythmical disturbances, of premonitory signs of accident as pallor, vomiting, or prostration, should be sufficient to keep the patient perfectly quiet. All effort should be avoided, every movement, for fear of syncope, which should always be anticipated. In case of actual accident, various methods of treatment have been employed without great success. The cardiac tonics, especially caffeine, are often employed, but Girard is sceptical of their action. The vasoconstrictor action of ergotine can be used in vasomotor paralysis. Strychnine is advised by various writers. Guthrie recommends the injection of a combination of sulphate of strychnine and sulphate of atropine. Injections of ether, and camphorated oil are also employed. The subcutaneous injections of artificial serum are of service. In cases in which there is considerable lowering of blood pressure, recourse can be had to venous injections. Their efficacy has been determined by Enriquez and Hallion in dogs at the point of death (following diphtheritic intoxication). Finally, faradization of the precordial region has appeared in some cases to be truly efficacious.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 2 1902.

When and How Should Operations Be Performed in Appendicitis?—A. Gallet reviews this subject and completes his paper by a table, in which he sums up the principle points: When a case of appendicitis is taken at the very start, within the first twenty-four hours, intervention should be immediate. This is rather theoretical than practical, as may be readily seen. There are two methods of procedure: Laparotomy, resection of the appendix, without drainage. Or Laparotomy, and if there are difficulties in consequence of former attacks, no resection, but tamponnage and drainage. In cases of appendicitis with localized peritonitis, the form most frequently observed, the operator, should wait unless there is a development of symptoms which denote the presence of a clearly purulent focus, or symptoms which indicate a peritoneal propagation. Then intervention should be immediate. Treatment may consist in favoring the tendency to encystment and to resolution by medical treatment. Or laparotomy and opening of the abscess may be undertaken. The appendix is not searched for; it is resected if it presents itself. Drainage is instituted. If there is generalized peritonitis, intervention is immediate, by the opening and drainage of the various foci. In cases of septic diffuse peritonitis, intervention is immediate. Multiple incisions are made in the abdominal cavity, with drainage. The cavity is washed out with hydrogen peroxide. In cases of appendicitis between attacks, intervention is strongly advised. Laparotomy with resection of the appendix is employed but no drainage. This method is sometimes attended with difficulties on account of the remains of adhesions and of inflammatory tissues.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 2, 1902.

The Edinburgh Medical Journal, October, 1902.

On the Treatment of Gangrenous Bowel in Strangulated Hernia.—George G. Hamilton reports two cases. The first was a femoral hernia. The patient being too ill for suture or even Murphy's button to be thought of, the author enlarged the femoral ring in every direction, chiefly with the finger, so that the bowel moved freely above the pinched portion. The loop of dead bowel was excised, and two small glass tubes tied tightly in. Death was expected in a few hours, but, to the doctor's amazement, the patient, a woman of seventy years, was pretty well the next morning, the tubes came away on the fourth day, and the tissues cleaned up. But on the tenth day the patient contracted bronchitis and died. In another case Murphy's button was used to unite the bowel after a gangrenous loop with a perforation in it had been removed. An uninterrupted recovery followed, and the button was passed on the tenth day.

Divison in Hand of Deep Branch of Ulnar Nerve.—George G. Hamilton reports the case of a young engineer who had received what was considered a trivial stab in the hand with a piece of glass six months previously. All the interossei were paralyzed, and the fingers contracted. The scar was below and a little to the palmar side of the pisiform bone. Sensation was normal. The diagnosis was forced upon the author that the deep branch of the ulnar nerve had been severed soon after it left the main trunk, and this proved to be the case when he cut down and found the two ends. These he brought together as well as he could with the finest silk suture. Within three months the patient was able to use his fingers for most kinds of small movements, his intermetacarpal spaces filled up, and when the author last saw him, he said he thought his hand was as good as it had ever been.

Two Cases of Tuberculosis of the Heart and Pericardium.—W. Maule Smith reports two cases found a autopsy to be cases of tuberculous myocarditis and pericarditis Such cases are rare, especially of myocarditis. The muscular system generally, and the cardiac muscle in particular, seem to be able to withstand tuberculosis markedly better than any other tissue in the body. The cause of this is not well ascertained. The disease usually manifests itself in tissues which are in a state of comparative rest, or where the blood stream is slowest. There is no other situation in the body where there is such frequent movement as in the heart muscle. The rate of the blood flow through the coronary arteries is considerably greater than in parts more removed from the heart. The two conditions are, therefore, inimical to the settlement and proliferation of the bacilli. In addition to these, the pure state of the blood, the products resulting from the muscular contraction and the simple mechanical action must all be against the tubercle bacillus obtaining a lodgement and setting up tuberculosis in the cardiac substance. When the length of time the bacillus requires before it can grow and multiply is taken in conjunction with these facts, it is scarcely surprising that the disease is so rarely found affecting this organ.

The Obstetrical Aspects of Idiocy.—William Gillespie considers the following conclusions justified by his investigations: The more frequent use of forceps with the object of preventing asphyxia, will tend to decrease the percentage of idiots to the general population. Some cases of congenital deafness are due to injury during parturition, and the percentage can, no doubt, be lessened by the rational management of labor. In children who have inherited a neurotic tendency, idiocy may follow an injury which would not have had such serious consequences in one that was descended from more stable stock. It is imperative that obstetricians not only study carefully the conditions which call for the use of the forceps, but that they acquire the skill and judgment necessary for their application, for there can be no doubt that in exceptional cases injury from forceps may cause mental defect or infantile cerebral palsy. Their judicious use, however, constitutes our best preventive treatment.—*The Cincinnati Lancet-Clinic.*

Shall We Make Our Consumptives Social Outcasts?—J. Howe Adams writes that in a region of the Adirondacks where, until two years ago, consumptives were treated with consideration and kindness, they are shunned and ostracized, and many hotels are announcing that no consumptives are taken. The feeling is not confined to the Adirondacks. We find legislatures of States seriously considering the exclusion of foreign consumptives; we find railroad directors studying the idea of separate cars for consumptives. Before we know it we shall have this unfortunate in the same class with the leper. The author suggests that local boards of health find the unsanitary spots, the unhealthy houses in the various cities, watch them; have them rebuilt and improved—register places, and not people. Too much stress has been laid on expectoration as practically the sole source of infection. Caged animals in zoological gardens are peculiarly liable to tuberculosis, and yet they are not spitting animals.—*The Medical Age.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 2, 1902.

Robert F. Weir, M.D., President.

The Wesley M. Carpenter Lecture; Relations of Physical Chemistry to Medicine.—Dr. John H. Huddleston delivered this lecture. He said that physical chemistry was practically a new science, and advances made in it had been very rapid. Medicine was chiefly concerned with it because of its bearing upon solutions. A solution is defined by physical chemistry as "a homogeneous mixture which cannot be separated into its constituents by mechanical means." Recent research had shown that wherever a solid is brought into the presence of a liquid, some of the solid dissolves; even a platinum vessel dissolves to a slight extent in the solution contained in it. Experiments made largely with the "semi-permeable membranes" had demonstrated the nature and degree of that part of the phenomenon of osmosis now known as osmotic pressure. By the electrolytic theory of dissociation was meant that certain substances when dissolved break up into fractions of molecules, called ions. An ion may be an atom or a group of atoms, but in any case it is a mass charged with electricity, either positively or negatively. The electricity borne by the atom may change many of its characteristics. It had long been known, the speaker said, that a dissolved substance lowers the freezing point of the solvent. An ion and a molecule lower the freezing point to some extent. Solutions of the same osmotic pressure have the same freezing point; hence, the osmotic pressure may be inferred from the freezing point. Solutions of equal osmotic pressure have the same boiling point, and the osmotic pressure may, therefore, be inferred from the boiling point. These relations had been thoroughly established experimentally, as well as demonstrated theoretically. For practical purposes the actual osmotic pressure of a solution was much less important than the relative osmotic pressures of different solutions.

The vegetable cell of the tradescantia is surrounded by a strong wall, lined on the inside by a semi-permeable membrane, which, in its turn, contains the colored contents of the cell. By starting with a solution whose osmotic pressure is greater than the cell, as shown by the contraction of the cell, and continually diluting it, a solution is finally obtained in which the cell will preserve its natural form. This solution then has the same osmotic pressure as the contents of the cell. Again, certain cells in the body may be assumed to be influenced by osmotic pressure in the same way. Red blood-corpuscles can be used as standards in a similar way, the test being a solution of a strength in which they just settle to the bottom. The number of ions and the degree of dissociation can be measured by three methods, the best of which is the conductivity method. When completely dissociated the conductivity is at its maximum. The percentage of dissociation is the actual conductivity of that solution divided by the maximum conductivity. The actual determination of this conductivity was by means of the Wheatstone bridge.

A study of dissociation showed that, as a rule, it increased up to a certain point with the dilution. For example, in a solution of 58.5 grams of sodium chloride in 1,000 liters of water it would be found that only 2 per cent. was dissolved as salt, the rest being sodium and chlorine. Direct experiment and theory both showed that the solubility and the dissociation of any salt was diminished by the addition of the solution of another salt yielding an ion in common. For example, the percentage of ions in a solution of sodium chloride was lessened by the addition of potassium chloride with its common chlorine ion, or of sodium nitrate, with its common sodium ion. Where dissociation did not exist, chemical activity probably did not exist. The vast difference between the chemical activities of different substances was familiar to all. It could be measured in various ways, as by the volumetric change resulting from the activity, but it could be best measured by measuring the amount of dissociation. As physiological activity might be fairly assumed to be based on chemical change, the physiological activity must be measured by the percentage of ions. To summarize: The determination of the freezing point of a solution gives the concentration and the osmotic pressure, and the determination of the electrical conductivity gives the amount of dissociation; that is, the percentage of ions—in other words, the chemical or physiological activity of the solution.

That almost all of the tissues of the body are semi-solid and bathed in fluids was a familiar fact, as also the fact that there is a continuous interchange of water, of dissolved material of both organic and inorganic material. This interchange may follow physical laws or be dependent upon, in part, at least, vital energy. It should be borne in mind that solutions are not comparable by percentages in dealing with the properties of bases and acids, for it is necessary to compare equimolecular solutions.

Absorption from the Intestine.—The intestinal wall, separating as it did two solutions, the blood and the fluid intestinal contents, was naturally considered to be a good place to study osmosis. Although the uninjured membrane will pass various organic materials from the intestine to the blood, experiment had shown that it would not pass them in the reverse direction unless injured—in other words, it was not a perfect semi-permeable membrane. The rates of absorption of different ions from the intestine were found to be in proportion to their characteristic physical weights.

Absorption from the Stomach.—Absorption from the stomach differed from absorption from the intestine, in that both salts and water were excreted into the stomach. Fluids swallowed were brought by osmosis to a pressure lower than the osmotic pressure of the blood, and one varying between comparatively narrow limits, and this took place before absorption began. The cause of this phenomenon was unknown. A certain amount of acid was loosely bound up with proteid and other material, and was, therefore, not free, though easily available for digestion. It was not, therefore, desirable to determine the amount of free hydrochloric acid, but the amount of physiologically available hydrochloric acid. It was, therefore, important to learn the concentration of the acid ions. This could be done by comparison with a solution of hydrochloric acid of known strength. This was done by ascertaining the electrical conductivity. It was interesting to note that Congo red produced its well-known reaction by virtue of its dissociation. The origin of the hydrochloric acid was supposed to be not in the glands themselves, but upon the free surface of the stomach wall, and was conditioned only by the irritation from the presence of the free chlorine ions there. This theory did not, however, take account of the relation of nervous influence to the quantity of hydrochloric acid.

Examination of the Blood.—The osmotic pressure of the blood was affected almost exclusively by the salts of the blood. Careful experiment had shown that the osmotic pressure in the maternal and the fetal blood was the same, and that in the body, milk, and other fluids are in equilibrium. The red corpuscles, the lymph spaces, and the kidneys are the chief factors in maintaining this standard. The red corpuscles had been proved to act like a solution in a semi-permeable membrane, *i. e.* they take up certain materials and exclude others completely. The internal pressure might become so great as to cause rupture of the corpuscle and the extrusion of the contained hæmoglobin. The effect of osmotic pressure upon the passage of matter through the lymph spaces was still doubtful, but it was probable that vital activity was here the controlling factor. The normal freezing point of the blood had been determined to be 0.56° C. below zero.

The Kidney.—It was of interest that solutions of salts to possess the same power of causing diuresis must have the same osmotic pressure. Urine was distinguished from the other secretions by having a different osmotic pressure from that of the blood. In the case of disease of the kidney on one side, the ordinary methods of examination, including catheterization of the ureters, had sometimes failed. Here, the determination of the freezing point of the urine might be of service in showing the functional activity of the kidney.

The Colloidal Solutions.—It had been very recently shown, the lecturer said, that the character of a solution was not lost if the particles were much larger than the molecules. Colloidal solutions were those in which the particles were of such size that, by their magnitude, they imparted certain physical characteristics to the solution. Thus, the colloids are viscid and form tenacious films; they form froth on agitation and separate on standing. Membranes had been made through which even ions could not pass, yet some membranes would pass some ions and refuse passage to others. Many substances, such as proteids, which had seemed hopelessly complex, may owe their complexity to some of these peculiar characteristics of their solutions. It had been found that albumin, albumose, and pepsis do unite with sodium hydrate and phosphate, but not with sodium chloride. It was not improbable that the therapeutic activity of a drug may, at times, be markedly influenced by the nature of the solvent employed. Physical chemistry had pointed out that bicarbonate of sodium, lithium salts and piperazine cannot have any directly solvent action on uric acid or the urates, although by exciting diuresis they might favor the elimination of these products. Dr. Huddleston said that he had made experiments to ascertain the disinfecting power of bichloride of mercury, bromide of mercury, and cyanide of mercury, each one of these mercurial solutions containing the same quantity of mercury. It was found that the bichloride had the greatest and the cyanide the least disinfecting power, as determined by the action upon certain spores. Other experiments showed that the greater the addition of ammonium chloride to mercuric bichloride the less the disinfecting power of the latter. The addition of sodium chloride to a watery solution of carbolic acid had been found to increase the disinfecting power of that acid.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held October 9, 1902.

Rowland G. Freeman, M.D., Chairman.

A Case of Infantile Stridor.—Dr. Charles Herrman presented an infant of three and a half months, who, a short time after birth, had developed a peculiar croaking inspiration. The intensity of the sound was not constant, and was most marked at times of excitement, or when suckling. The general health was good, and there was no cyanosis. The speaker said that by some authorities it was supposed to be the result of a congenital deformity of the larynx, an exaggeration of the infantile type of larynx. Postmortem examinations on one or two of these children dying of some intercurrent disease had shown no enlargement of the thymus or of the glands in the mediastinum. The condition usually disappeared spontaneously by the second year.

Dr. W. P. Northrup said that he had just seen the counterpart of this case in a child of five months. At the end of the first month the infant had developed this peculiar inspiratory sound, called by the French "the croaking of frogs." According to the mother, the sound had gradually increased in intensity, until it had become so loud when the little one was asleep, as to make it an annoyance in the house. The baby was free from rickets and, apparently, from adenoids, and was healthy in every other respect. He was disposed to accept the theory that the folds of mucous membrane becoming congested, especially the arytenoepiglottidean folds, are drawn over into the larynx, and then break away, thus giving rise, mechanically, to this peculiar whistling inspiration. The fact that the infant just presented could instantly control the sound would seem to negative the view that had been presented by one author, that it was paralytic in origin.

Some Observations in the Children's Hospitals of Paris and London.—Dr. L. E. La Fetra read this paper. He said that one defect of these hospitals was the very large number of patients. Both London and Paris were much better supplied with hospital accommodations for children than was New York City. In the three principal London hospitals for children it was noted that there were more physicians on the staff than here, thus allowing of better work being done. The work in the out-patient department was worthy of special notice, chiefly because of the number of clinical assistants, and the arrangement of the rooms so as to facilitate a thorough yet expeditious examination of the patients. Printed directions with regard to feeding and care of the children were given to the mothers. The hospitals of Paris were found to have an abundance of air, light, and ground, and to be laid out on the pavilion plan. The responsibility for the out-door work was shared in turn by the visiting physicians of the hospital. Each student or visitor was provided at the gate of the hospital with a gown, and an additional gown was worn in each pavilion for contagious diseases. Antitoxin was the routine remedy for the curative and prophylactic treatment of diphtheria. Scarlatinal nephritis was found to be very rare here, and this was attributed to the great care taken in cleansing the mouth, the idea being that this nephritis is due to a special streptococcus, but, the speaker added, that it was well known that scarlatina in France is very mild. There seemed to be a great need in Paris for a milk commission to raise the standard of the milk supply. The value of percentage feeding did not seem to be recognized. It should be remembered, however, that wet nurses are easily obtained there in private practice. The hospital physicians give a great deal of time to their work in the hospitals. Students are assigned to work up special cases in the wards, thus lightening the work of the house staff at the same time that the students are interested and instructed.

Dr. W. P. Northrup said that the intubation tubes used in France were very different from those devised by Dr. O'Dwyer, being short and having a large bulge, and this explained the facility and popularity of the method of "expressing" the tube. It was quite remarkable that many of the portable isolating rooms used in the hospitals were made of partitions which did not reach fully up to the ceiling. The upper part of the partition is glazed so as to let in sufficient light and allow of the supervision of all the isolated patients in the ward.

A Review of Some of the Older Writings on Infant Feeding.—Dr. Samuel McC. Hamill of Philadelphia was the author of this paper. Regarding maternal milk, he said that for the past two centuries all authorities had agreed that this was the best of all foods for infants. There were three principal varieties of substitute feeding, viz., wet nursing, direct nursing from animals, and the use of artificially-prepared foods. Direct nursing from animals had many repellant features, to say nothing of inconveniences, which made it an almost impracticable method. The goat, the ass, and the cow were the animals which had been chiefly used in this way, and it had been found that the goat was the most manageable because, in time, it became attached to its nursling. The first author who had given definite directions about the modification of milk, was Morse, who, in 1794, recommended one part of cow's milk to be mixed with two parts of water. This was the same dilution recommended by the elder Meigs in

1850. It was shown that the older writers had recommended the use of gruels for the distinct purpose of breaking up the hard curd of cow's milk. As long ago as 1825 Dewees had recommended the use of fresh milk from one cow, two parts with one part of water, and had directed that the milk should be heated and prepared separately for each feeding. Up to 1853, when the older Meigs had published his well known mixture of cream, milk, gelatin, and arrowroot, most writers had followed the directions of Dewees. Dr. Cummings, a physician of Williamstown, Mass., had published in 1859, a book on infant feeding, in which the first really scientific effort at milk modification and percentage feeding was made. This author appreciated the necessity of varying the dilutions at different ages, and insisted that, as cow's milk must be diluted in order to reduce the proteid sufficiently, there resulted a marked deficiency of fat, which was to be made up by the addition of cream. Dr. Hamill said that in 1786 the nursing bottle of glass had been invented. Prior to that time a cow's horn, capped with a piece of parchment, or with a heifer's teat for a nipple, had been in vogue. The first reference found to a rubber nipple was in a book by Tanner, published in Philadelphia in 1861.

Dr. W. P. NORTHRUP said that at the present time in Naples, it was common for young infants to nurse directly from goats, while the older children were fed on goat's milk of full strength.

The Recent Meeting of the Pediatric Section of the British Medical Association.—Dr. W. P. NORTHUP gave, in a brief and interesting talk, his impressions of this meeting.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 7, 1902.

JOSEPH COLLINS, M.D., PRESIDENT.

A Case of Generalized Scleroderma.—Dr. B. SACHS presented a lady, twenty-four years of age, with ordinary hypochondriacal neurasthenia, whom he had first seen six years ago. When next seen, last year, she stated that during the past few years she had noticed that the upper and lower extremities had begun to be stiff and more or less painful on movement. She was not aware at the time that there was anything especially wrong with her face. At present the face shows a very marked form of scleroderma, and she also has distinct sclerodactyly. Six months ago there was so much retraction of the upper lip, as a consequence of the retraction of the skin, that the gums were constantly exposed. The hands showed marked tenseness and glossiness of the skin, attenuation and clubbing of the fingers, and an apparent subluxation of the middle finger at the metacarpophalangeal articulation. An *x*-ray photograph showed that the latter was due to the wearing away of the bone under abnormal pressure. There was also a general scleroderma in this patient, extending from the forehead to the middle of the abdomen. The lower extremities were only sclerodermatous in certain areas. There were also some areas of leukoderma. The speaker said that this woman had shown a certain amount of improvement under thyroid medication. She had taken as much as eighteen grains a day without detriment, and had also had warm baths and exercises with the object of improving the condition of the integument and underlying tissues.

Dr. GEORGE W. JACOBY said that he had been one of the first to act upon Dr. Sachs's suggestion regarding the use of the thyroid extract, and he was convinced that this treatment accomplished something. About a year ago he had himself reported two cases, in children, in which the skin had become almost perfectly pliable as a result of thyroid treatment. The changes in the fingers had been very much more marked than in the case now under discussion. Of course, these pathological conditions did not retrograde. He did not think the pressure of the retracting skin was sufficient to explain the marked bony changes observed. In his opinion the thyroid treatment was the only one that held out any prospect of success, and it was particularly useful in children.

Dr. JOSEPH FRAENKEL said he believed there were two types of scleroderma, the localized and the generalized. The latter appeared to him to be an expression of a rheumatic tendency. For the last four months he had had a case under observation which had done very well under antirheumatic medication, particularly with the use of the salicylates. Ordinarily, the thyroid medication seemed to be the best method.

Dr. JOSEPH COLLINS said that he had had some experience with the thyroid treatment, and, while he had observed improvement, the results were not at all comparable with those reported by Dr. Sachs and Dr. Jacoby. All that he thought the thyroid did was to diminish the subcutaneous fat. This, of course, made the skin much more pliable over the affected area, and reduced the mask-like appearance of the face. In his opinion scleroderma was a disease of the spinal cord and of the sympathetic fibers and cells within the spinal cord. The symmetry, chronicity, course, and termination were all explicable on this theory. He hoped soon to have an opportunity of making a post-mortem examination upon a marked and advanced case of general scleroderma. In that patient sensory changes were occurring, which pointed strongly to involvement of the conducting pathways of the spinal cord. As young persons have a marked accumulation of subcutaneous fat, and this fat could be very readily increased or diminished, it was easy to explain the good results just reported by Dr. Jacoby.

Dr. SACHS said that in the patient he had just presented there had been an extremely disagreeable appearance of the face a few months ago, resulting from the attenuated state of the nose, a part having very little subcutaneous fat; yet this part had very decidedly improved under the thyroid medication. He would be greatly surprised if scleroderma proved to be an affection of either the spinal cord or of the sympathetic system. The disease seemed to be diametrically opposite to two other diseases—acromegaly and myxœdema. He was inclined to think that scleroderma was possibly a general glandular affection, involving not only the skin but the subcutaneous tissues, and even the bones.

A Case of Myotonia.—Dr. EDWARD D. FISHER presented a young man who had first come to his clinic about one week ago. The man was twenty-four years of age, an electrician by occupation. He was apparently well up to the time of enlistment in the Spanish-American war. Over one year ago the left foot began to twitch on attempting to walk. In February, 1902, the right leg became involved, and later the muscles higher up, even in the back. At present all of the muscles below the ribs become more or less contracted on attention. There is no loss of sexual power or loss of sensation. The electrical reactions are normal. On standing up there is a twisting of the body and spasm in the feet, the latter causing him to walk on the outer borders of the feet. The process had lately extended upward, so that there was now a mild affection of the muscles of the hands and arms. The diagnosis seemed to rest between myotonia and some functional disorder.

Dr. B. SACHS said he had had an opportunity of examining this man about two weeks ago, and had been impressed with the possibility of its being a hysterical condition. He had examined the muscles electrically, and had found them abnormal. There were distinct evidences of a myotonic reaction, a long-continued wave which started in one part of the muscles and spread up slowly between the electrodes. Moreover, with the object of excluding hysteria he had at first applied a current which was very mild, not letting the patient know that he was doing so. As the current was gradually increased up to the point which should produce a muscular contraction this wavelike contraction was observed.

Dr. J. Fraenkel remarked that he had seen this patient at the clinic, and that Dr. J. Ramsey Hunt had been unable to obtain the myotonic reaction.

Dr. George W. Jacoby said that these cases emphasized the difficulty of making the differential diagnosis between myotonia and hysteria. He had presented a case of myotonia acquisita to the American Neurological Association. All of the myotonic symptoms were present, and there were the electrical and mechanical reactions characteristic of myotonia. A microscopical examination, however, yielded results that were difficult to reconcile with this diagnosis. Dr. Jacoby said he made a bad prognosis, and had subsequently learned that the man, after winning a lawsuit against a railroad company, became perfectly well.

Dr. Collins thought if the diagnosis of hysteria major was to be made there should be present more stigmata than merely myotonia.

Dr. E. D. Fisher said that the general aspect of the patient had led to the suspicion of a neurosis, but after careful examination the diagnosis of myotonia had been made. The electrical examination had been made last June, and at that time no electrical changes were observed. The man's appearance was certainly that of a neurotic individual.

Radiographs of a Tumor of the Brain.—Dr. George W. Jacoby presented some *x*-ray pictures from a recent interesting case. He said that he had been taking these pictures in such cases for a number of years, but until now the results had been very disappointing. The diagnosis in the present case was a tumor of the brain in the mid-Rolandic region, and the patient had been operated upon about two hours ago. The tumor had been found in the position diagnosed, and corresponding to that indicated by the radiograph.

A Case of Brain Tumor (?).—Dr. William M. Leszynsky presented a man, thirty-one years of age, first seen a few weeks ago. Ten years ago he began to have attacks of headache followed by vomiting. At first, there was only one attack each month, but more recently they had recurred about once a week. Six months ago the headache became more intense, and was associated with vomitin and vertigo, and he was in bed for three weeks. On getting up he had diplopia, and three months ago he became blind, and since then had been unable to walk. There was now moderate general headache and vertigo. There was no history or evidence of syphilis, and no history of alcoholism or of infectious disease. Examination showed no tenderness on percussion over the skull. There was some rigidity of the muscles of the back of the neck; both pupils were dilated and immovable, not reacting to light or to convergence. Reflex winking was absent on the left, but well marked on the other side. There was paralysis of both right and left abducens nerves, paresis of both internal recti and an inability to converge. Vision was completely absent in both eyes, and there was marked neuroretinitis on both sides, but no choked disc. There was partial paralysis of the seventh nerve and of the orbicularis palpebrarum. There was an actual deviation of the tongue tó the left. The grasp was good on both sides. There was no paralysis of the lower extremities, yet he was absolutely unable to stand. There was no apparent weakness of the trunk muscles. The case was presented for diagnosis. The question arose as to whether there was a tumor of the cerebellum originating in the vermis, or one that had extended to this part from the corpora quadragemina. If the pyramidal tract were not affected it was possible that there might be a secondary meningitis.

Dr. B. Onuf suggested that there might be a tumor of the pons.

A Case of Tabes with Marked Bulbar Symptoms.—Dr. I. Abrahamson presented a man of forty-four years, seen at the clinic in the latter part of September. There was a history of marked alcoholism. The present illness dated back to last spring, when diplopia developed, quickly followed by ptosis and lachrymation. The man had lost thirty pounds since that time, and difficulty in mastication and in urination had developed, along with hoarseness and various paræsthesiæ of the throat. The temporal arteries were tortuous, the patient was badly nourished and presented evidence of degeneracy. The Romberg symptom was present, and the motions of the eyes were restricted. There was marked wasting of both temporal and masseter muscles, with greatly diminished reaction to both electrical currents. The optic nerve showed beginning white atrophy. The knee-jerks and Achilles reflex were absent on both sides, while the bulbar reflexes were lively. Tactile sensibility was nearly normal. The chief feature of the case was the extensive cerebral and nuclear involvement. The case was evidently one of tabes with very marked bulbar symptoms.

Differential Diagnosis of Multiple Sclerosis.—Dr. B. Onuf presented a paper on this subject. He quoted from the literature to show that it was probable that this term, multiple sclerosis, referred to a symptom complex, representing most varied pathological processes. The diseases most apt to be confounded with it were diffuse sclerosis, pseudosclerosis, cerebrospinal syphilis, general progressive paresis, and a number of other diseases, such as tabes, ataxic paraplegia, and transverse myelitis. Diffuse and pseudosclerosis had a symptomatology so similar to that of multiple sclerosis that he did not feel the differential diagnosis could be clearly made. The multiplicity of the lesions of cerebrospinal syphilis and the recurrence of the symptoms after intervals of comparative freedom from them bore a close resemblance to multiple sclerosis. It was evident, therefore, that the diagnosis must be founded on a complete clinical picture rather than on one or two individual symptoms. The value of antisyphilitic treatment was great as a diagnostic aid, but the results were not wholly reliable, particularly when marked improvement was not noted within a period of about two weeks. Spasticity was just as frequently observed in syphilis, and the intentional tremor he had seen very typically developed in a case of undoubted cerebral syphilis. Fairly developed nystagmus pointed very strongly to cerebral syphilis as against disseminated sclerosis. Scanning speech was a strong symptom in favor of disseminated sclerosis as against syphilis. There were two symptoms which he considered of great importance: (1) the facial expression, and (2) an emotional state, associated often with marked euphoria. These two symptoms were relatively rare in syphilis. Optic neuritis was present in a large percentage of cases of multiple sclerosis, and was often the only symptom in the early stages; however, optic neuritis was very common in cerebral syphilis, though it was more apt to be attended by retinal hemorrhages. The fact that multiple sclerosis was often ushered in by some acute disease was a point of some diagnostic importance. The speech disturbance in general progressive paresis was often quite marked; indeed, this affection should not often be confounded with multiple sclerosis. The number of spinal diseases that might be simulated by multiple sclerosis was very great. In doubtful cases the presence, besides the spinal manifestations, of symptoms pointing to multiple cerebral involvement would speak in favor of disseminated sclerosis, as would also the symmetry and regular distribution of the spinal symptoms. The speech of bulbar palsy might be very much like that of multiple sclerosis, and the patient might also be distinctly emotional.

Dr. Fisher thought multiple sclerosis was most likely to be confounded with cerebral syphilis and general paresis, and yet it was only at certain stages that even here any difficulty existed. The tendency to stupor and attacks of prolonged sleep, and the ocular palsies were characteristic, and were not observed in insular disease.

In general paresis the flattening of the face the tremor, and the articulation were quite similar, but the mental state was quite different. At times multiple sclerosis might be confounded with hysteria. The disease being very slow in its progress, years might elapse before the true diagnosis of insular sclerosis could be made. It should be borne in mind that insular sclerosis sometimes occurred in young people, at the age of sixteen or eighteen years, a point of differentiation from cerebral syphilis.

Dr. Onuf agreed with Dr. Fisher that the tendency to somnolence was ordinarily a strong symptom in favor of syphilis, and admitted that it was sometimes difficult to distinguish the disease from hysteria.

Arterial Disease in Comparatively Early Life.—Dr. E. D. Fisher read a paper with this title. He said that if one had not established one's self in some definite line of work by the age of forty, one would rarely succeed. This was the law of life. Having excluded syphilis, kidney disease, diabetes, alcoholism, and old age, there would still be a number of cases of arterial disease having a different etiology. He was of the opinion that cerebral hemiplegia was more than ordinarily common at the present period of our national development. There was an intensity in the pursuit of an object in the Anglo-Saxon race not present in the Latin races; this led us to a very large consumption of tissue. He believed that the so-called "strenuous life" led to fatty degeneration of the cardiac and arterial muscular tissue. If this view were correct, then the means of prevention were obvious and important. Our social system in the large cities was one of anxiety and overwork. There should be less straining after living, as is the case with the very rich, and a stronger desire for culture and moderation.

Dr. W. B. Noyes raised the question as to whether, in the treatment of so many diseases of the nervous system with strychnine, physicians were not committing a grave error. The effect of this drug on the arteries was not closely studied, and it had occurred to him that in cases like those described in the paper, in which there was, in his opinion, arterial disease, the persistent use of a drug like strychnine, which increases the arterial pressure, was actually harmful, and more than counterbalanced the beneficial action of the remedy upon the peripheral nerves. He believed that many of those present could bear him out in the statement that iodide of potassium frequently benefited many cases in which there was no syphilitic taint, probably by its effect on the vascular system. He would like to hear from others regarding this view that strychnine and iodide of potassium are,to a certain extent, antagonistic in their action on the vessels.

Dr. Leszynsky said he could not agree with Dr. Fisher in the contention that the so-called strenuous life produces cerebral and arterial degeneration, unless this was accompanied by alcoholism, syphilis, or some other toxic cause. He had never seen a patient under forty years of age with a cerebral hemorrhage or endarteritis unless there was some discoverable cause which would lead one to the belief that such conditions had previously existed.

Dr. Sachs said it was interesting to consider whether there was really arterial disease in early life sufficient to lead to apoplectic attacks. Personally, he could not recall a single case of cerebral hemiplegia which was not due to arteriosclerosis, syphilis, or embolism, or was the accompaniment of renal disease. There was only one other vascular degeneration occurring early in life, *i. e.* a fatty degeneration of the artery, and which explained the very early apoplectic attacks in children. When he had been able to exclude embolism, renal disease, and syphilis he had always come to the conclusion that the case was one of early arteriosclerosis.

Dr. Joseph Collins said that he found it very difficult to talk upon arterial *disease*—not sclerosis. He was thoroughly convinced that chronic degeneration of the tunica media, arteriosclerosis, was a disease of the strenuous life, and that alcoholism, rheumatism, syphilis, and the so-called metabolic diseases had very little to do with this. A deficient heredity was one of the contributing causes. Another was chronic indigestion of any kind and a third was worry with work. These were more potent causes of arterial degeneration than syphilis, alcoholism, and bad habits. The last-named conditions caused periarteritis and endarteritis. A second great class of cases was dependent upon infections; some would put these as the first and more important class. We had been taught as students that arteriosclerosis was a disease occurring in those past fifty, but he maintained that this was not true, and that when the disease began at that time it was nothing more than a natural process at that age. A person of sixty-five or seventy years of age becoming ill with an infection like pneumonia usually had the disease in an exceedingly mild form. He would further contend that arteriosclerosis was, at the present day, the scourge of humanity, and that here was no organic disease of the nervous system that could compare with it in its effect upon the production of disease.

Dr. Leszynsky thought the last speaker had begged the question with regard to young subjects. If the strenuous life reacted upon digestion and interfered with assimilation it caused an intoxication or an infection, and in this way set up an arteriosclerosis. He did not think any proof could be adduced to show that the strenuous life alone produced arteriosclerosis.

Dr. Fisher, in closing, said that a man over forty years of age would rarely start out in a new line of work, although he might continue to do much very good work in old channels up to quite late in life. If he had understood the remarks of Dr. Collins, he did not think their opinions were very much at variance on this topic. By arterial disease he meant any morbid condition of any part of the arteries.

Albuminuria Following Severe Exercise in Healthy Persons.—T. P. Dunhill and S. W. Patterson examined the urine of a number of young men engaged in racing. Analysis of the results obtained showed that as the severity of the exercise was increased, the urines of those members which had previously contained traces of albumin showed larger amounts, and urines which had previously been free contained proteids. After the contest itself (two miles) every man passed urine containing over .05 per cent., except one, whose urine had .02 per cent. That albuminuria occurs with greater readiness in some individuals than in others, was clearly shown. In a few cases during training the urine passed in the morning contained a trace of albumin. This was most obvious the day after the exercise on the river had been particularly severe. A further point, which was incidentally discovered, was that in different urines the sensitiveness of boiling, and ferrocyanide of potassium with acetic acid, as tests for proteid, varied considerably. Some samples gave distinct indication of the presence of proteid with the one and not with the other.—*Intercolonial Medical Journal of Australasia.*

Tubercle Bacilli in the Nail-dirt of Children.—In the *Berliner klinische Wochenschrift*, May 17, Kornel Preisich and Aladar Schütz give an account of the examination of the nail-dirt of sixty-six children with a view to discovering the frequency of the occurence of tubercle bacilli therein. In fourteen cases, or 21.2 per cent., this was accomplished. The children were not selected from tuberculous surroundings. Of the fourteen cases in which tubercle bacilli were found nine gave a history of hereditary tuberculosis, and in every case where a history of hereditary bone tuberculosis was given, bacilli were found. These investigations would seem to demonstrate the importance of the nail-dirt of children in the spread of tuberculosis.

Clinical Department.

ACUTE INTESTINAL AUTOINTOXICATION WITH SYMPTOMS RESEMBLING THE ONSET OF CROUPOUS PNEUMONIA.

By DOUGLAS SYMMERS, M D.,
PHILADELPHIA.

The literature of recent years has added materially to our knowledge of the various phases of intestinal autointoxication, but, as far as I have been able to determine, it contains no reference to a series of symptoms at once so startling, so sudden, and so violent in nature as to be suggestive of the onset of an acute infection, more particularly, croupous pneumonia. While acting as resident physician in the Philadelphia Hospital I met with four such cases within as many weeks. At the time few definite notes were taken concerning the various cases, and the following account is drawn largely from memory:

Case 1.—The patient was a man, about fifty years of age, of muscular proportions, and was admitted to the surgical wards by Dr. G. E. Pfahler, the assistant chief resident physician during my service as night interne. At the time of Dr. Pfahler's first examination, which was made in the receiving ward about eight hours before the appearance of the symptoms noted below, there was nothing which pointed to the existence of any form of pulmonary disease. The patient complained of nothing more serious than an obstinate leg ulcer, chronic in character, and unattended by any acute inflammatory or suppurative process. Consequently he was referred to the surgical side, where, shortly after nightfall, he developed a violent chill lasting about three-fourths of an hour. The axillary temperature was elevated perhaps 3° or 4° F., the pulse was rapid and full, the patient extremely restless and actively delirious. The face and chest were bathed in perspiration. The respirations were about fifty to the minute. Dr. Pfahler examined the patient's chest as thoroughly as the circumstances permitted. He was able to detect a limited area in the left lower scapular region, over which there was distant bronchial breathing. Croupous pneumonia, central in origin, was suspected. Morphine gr. $\frac{1}{4}$ and hyoscine hydrobromate gr. $\frac{1}{100}$ were administered, hypodermically. A house enema, known and used in the Philadelphia Hospital as a "glycerin-mag" enema, and composed of a concentrated solution of magnesium sulphate and glycerin, was given, and a free passage followed almost immediately. Supporting treatment was ordered throughout the night, as indications arose. The patient soon became quiet, the symptoms retreating with surprising rapidity. I saw him repeatedly throughout the balance of the night, and early the following morning he was sleeping soundly, respirations, pulse, and temperature were normal, and the above-described symptoms, at first so alarming, had given place to rest. There was no return.

In this case the left leg revealed an ulcer, apparently of several years' duration, and there were no signs of pus formation to account for the disturbances present. The prompt, almost instantaneous and permanent relief which followed the use of an enema, together with the stimulating and quieting effects of the hyoscine and morphine, seemed to point almost conclusively to autointoxication of intestinal origin as the sole disturbing factor.

Case 2.—The patient was a woman about eighty years of age, pale, weak, and emaciated. She was confined in one of the detention wards awaiting an examination as to her sanity. The mental condition was plainly one of senile dementia. Early one morning, after a night during which a number of the patients had been most tryingly demonstrative, she evaded the scrutiny of the nurses on duty, and, in attempting to arise from bed, fell, striking her forehead and sustaining a short, lacerated wound in the region of the left angular process. A single stitch of silkworm gut was inserted, the wound was dressed, and the patient was returned to bed. During the course of the succeeding night, about eighteen hours after the receipt of the injury, I was called to see her, and found her, in a severe chill, propped up in bed, extremely dyspnœic. Her pulse was rapid, intermittent, and irregular, filiform in character rather than full, and the vessel itself was atheromatous. The skin was hot and dry, and the thermometer in the axilla registered 3° or 4° F. above normal. The heart was beating abortively. The second aortic sound was accentuated, and the muscular tone seemed impaired. No murmurs were detected. A careful examination of the lungs disclosed dulness at the left apex, anteriorly. Auscultation at this point revealed the presence of numerous small "sticky" râles, so characteristic of the lung which is undergoing the degenerative changes incident to advanced tuberculosis. Posteriorly the breath sounds were universally bronchovesicular in type, but no râles were heard in this region. The wound on the forehead was perfectly clean.

Stimulant and eliminative treatment was ordered, the latter in the form of the house enema of magnesium sulphate and glycerin. About an hour afterward I saw her again. She was greatly improved. Later in the day the siege was over, the respirations and temperature were normal, the heart was acting more evenly, and the pulse was lower and of a better tone, the general aspect of the case being one of comparative quiet. An examination at this time confirmed the original diagnosis of tuberculosis of the left apex, and added signs of beginning infiltration of the right.

At first glance the symptoms looked not unlike those of pneumonia. The apical involvement suggested some form of beginning bronchopneumonic phthisis. The subsequent course of the case, however, and the physical examinations, negatived both ideas, while the result of treatment seemed to support the view that the condition was neither more nor less than a sudden and severe constitutional reaction dependent upon the rapid absorption of the toxic products of intestinal decomposition.

Case 3.—The patient was a man, seventy-seven years of age, an inmate of the insane pavilion of the Philadelphia Hospital, suffering from senile dementia. I saw the case with Dr. Walter S. Patterson, the assistant physician in this department. The patient was a thin, weak old man, whose arteries were markedly atheromatous. One morning he was found in the midst of a violent chill, huddled up in bed with the sheets drawn closely around his chin, limbs crouched together, teeth chattering violently, the face and fingers deeply cyanosed. The skin was hot, dry, and rough to the touch. The thermometer in the axilla registered a temperature of 103° F. The respiratory movements were abbreviated and rapid, numbering fully 50 to the minute. The pulse was thin and 120 to the minute, the vessel hard, incompressible, small, and extensively beaded by atheromatous deposits. An examination of the lungs disclosed decided dulness at both bases, not reaching, however, the intensity of flatness. The patient's mental condition would not permit the determination of the degree of vocal or tactile fremitus, in that he would not speak above a whisper. Auscultation revealed distant breath sounds. Liver dulness did not extend to any depth below the costal arch, in the right mamillary line. The heart was not markedly displaced. There were, however, evidences of hypertrophy. No murmurs were detected. In view of the stated facts, and because of the bilateral distribution of basal dulness, pleural effusion was regarded as improbable, if not impossible. At this time the urine was not examined, although later albumin and tube casts were found to exist. There was no surface œdema and no valvular lesion in the heart. For these reasons, and because of the character of the physical signs at the bases of the lungs, bilateral hydrothorax was eliminated and a thickened pleura determined upon as the cause of the dulness and the distant breath sounds.

Stimulants were ordered, and a glycerin-magnesium enema, with the result that the patient almost instantly subsided into his accustomed state after the lower bowel had been emptied by the enema. The chief attendant in the ward told me later that he had seen the same patient suffer precisely similar attacks on previous occasions, the storm arising suddenly, raging furiously for a few hours, only to pass away, leaving behind no evidences of its existence save, perhaps, a more pronounced degree of weakness than before. He could not say definitely, however, if, in every instance, free bowel movements had produced the same prompt cessation of symptoms, but his impression was that such had been the case.

CASE 4.—I saw this patient with Dr. E. H. Bainbridge, who, at the time, was the interne in charge of the Gynecological and Obstetrical Division of the Philadelphia Hospital. The patient was a well-developed woman, about forty years of age. Seven days previous to the onset of the symptoms described below she gave birth to a healthy child. Her labor resulted, however, in rather an extensive laceration of the perineum, which Dr. Bainbridge immediately repaired. The patient was proceeding, apparently, to recovery when, about 1 o'clock on the morning of the seventh day, she suddenly developed a series of severe chills. The respirations rose to 40 or more to the minute. Her pulse was rapid, full, and bounding. Her cheeks were suffused in a typical mahogany flush, both pupils were dilated, the eyes were clear and bright, and the facial expression was one of intense anxiety. The axillary temperature was a trifle above 104° F. The patient was very restless, and her skin was hot and dry. An examination of the lochia did not reveal any particularly disagreeable odor. The lungs showed a normal degree of tactile fremitus over the anterior chest. Posteriorly, tactile fremitus was universally but mildly exaggerated. The percussion note over the entire posterior chest was clear and high-pitched, almost the tympanitic note of pulmonary engorgement. Auscultation developed harsh breathing over both lungs, anteriorly and posteriorly. There was no suggestion of râles. Partly in view of the general symptoms, and partly because of the interpretation of the physical signs referred to the chest, a provisional diagnosis of croupous pneumonia was made, a more positive opinion being reserved until the further development of physical signs and the disclosures of a vaginal examination.

Dr. Bainbridge at once ordered active eliminative treatment addressed to the kidneys and bowels, the latter in the form of a "glycerin-mag" enema. In addition he prescribed supporting treatment. The case was carefully watched during the balance of the night. The patient responded well to treatment, and within an hour or so her temperature fell to normal, her pulse resumed a quieter tone, the chills ceased, the respiratory movements were normal in depth and frequency, and the entire outlook was complacent and in every respect promising. The chest examination at this time was negative.

Several hours after the subsidence of these symptoms a vaginal examination disclosed a quantity of pus at the site of the perineal stitches, and a soft, boggy, cervix. The patient was prepared for operation, the cervix dilated, and the uterus thoroughly curetted, emptied of a quantity of putrid material and drained, the vaginal stitches were removed, and the mucous surface rendered as clean as possible. The patient made an uneventful recovery.

The appearance of this patient was at once suggestive of the onset of croupous pneumonia—the flushed face and anxious expression and the rapid respiratory excursions. A more detailed investigation of both signs and symptoms seemed to lend color to this view. The discovery of putrefactive matter, however, was one of more than passing import. Here, again, active eliminative treatment resulted in the rapid relief of all symptoms—a relief extending over a period of several hours. Whether or not these symptoms, including the violent dyspnœa, would have been counterfeited had not operative procedures been instituted and well carried out, is a question. Those who describe sapræmia and true septic conditions do not speak of dypsnœa as a symptom. That it occurs in intestinal autointoxication, which, after all, is but a form of sapræmia, seems certain. Therefore, it appears reasonable to assume that this case represented intestinal autointoxication reenforced, it may have been, by the products of putrefying areas, existing in the birth canal under pressure, and, perhaps, by toxins from the pus-bearing area around the perineal stitches. It is probable, however, that the greater portion of these toxic agents was absorbed from the large intestine, since complete and thorough evacuation of this viscus resulted in prompt relief, the improvement having been maintained up to the time of operation, and the operation itself having assured more or less immunity from similar seizures by removing the contributing elements. It also seems probable that sapræmic symptoms, depending upon the absorption of toxic products arising in the birth canal, would have manifested themselves at an earlier date.

Conclusions: 1. From a study of these cases it appears that intestinal autointoxication is capable of producing symptoms urgently suggestive of the onset of croupous pneumonia.

2. In the absence of definite physical signs of pneumonia, diagnosis should be deferred until after the bowels have freely moved. For example, we have only to await the result of such treatment, and, if the symptoms persist, a pneumonia, originally central, may display itself at the periphery.

3. This form of intestinal autointoxication, if unrelieved, may be capable of so reducing the vital resisting powers of the pulmonary tissues as to permit the implantation and multiplication of those organisms commonly regarded as active in the causation of pneumonia. In other words, it is to be considered, in isolated instances, a contributing factor in the production of this form of pulmonary disease—a view which finds support in the statement that ordinary sapræmia tends to cause congestion in various organs. (J. C. Da Costa, "Modern Surgery," p. 137.)

4. The dyspnœa is to be accounted for in one of two ways, possibly by a combination of both. First and most important in its production is the irritating action of toxic materials upon the respiratory

center in the medulla oblongata, as in the dyspnœa which sometimes attends uræmia and diabetes. A second and closely allied explanation refers a similar property to the warm blood of the febrile state, which, according to Landois, is a direct irritant to the respiratory center. While it is admissible that this action obtains in some cases, it cannot, in the vast majority, be regarded as more than a contributing element, for there are many condition in which high temperatures prevail without any marked interference with the function of respiration. On the other hand, both pyrexia and toxæmia may exist without dyspnœa, so that here there is a discrepancy to be explained. In this instance it may be that the toxic elements are not sufficiently irritating to disturb the equilibrium of the respiratory center. One need not trespass beyond the bounds of reason to assume that certain toxic materials may be so altered upon exposure to the elevated temperature of the blood as it exists in the febrile period, to be rendered innocuous. So, too, one has but to follow the same line of thought, and it becomes equally reasonable to assume that other chemical bodies, comparatively, if not entirely harmless in their original state, may, when injected into warm blood, be changed into toxic substances sufficiently irritating to produce marked disturbances in the delicate structures which govern the vital functions.

5. The result of treatment in such cases as I have described depends, first, upon the fact that the enema removes from the large bowel those particles by virtue of whose decomposition by putrefactive bacteria toxic substances are generated, and thence carried into the general circulation; and, second, that stimulant drugs support the vital centers until these poisonous bodies are eliminated or destroyed, after which the organism finds and maintains its accustomed state.

In closing, I beg to return my sincerest thanks to Dr. D. E. Hughes, chief resident physician in the Philadelphia Hospital, for his kindness in permitting me to publish these cases and for valuable suggestions.

ATRESIA OF THE VAGINA.

By LUCIEN LOFTON, A.B., Ph.G., M.D.,
BELPIELD, EMPORIA, VA.
EX-PRESIDENT SEABOARD MEDICAL ASSOCIATION OF VIRGINIA AND NORTH CAROLINA.

Recently there came under my professional care a little girl, four years of age, who presented rather an unusual condition; that of atresia of the vagina. The child had been suffering with "falling spells," as the mother termed it, for the past eighteen months.

The case presented the following brief history: Minnie S., aged four years, of robust appearance. Mother neurotic; father healthy and strong; had suffered for a year and a half from slight spasms. She would begin turning around, and suddenly, with a cry, throw the arms above the head and fall, sometimes on her face, but generally upon the back. In a few minutes she would recover, look dazed, arise, and walk away, staggering as she went. She was never known to sleep directly after an attack. She had been treated with nerve sedatives by several physicians, without permanent relief.

After hearing this brief history, I suspected some organic derangement. Having the mother strip the child, I went carefully over her, beginning at the head; meantime, securing no history of a fall or trauma of any consequence. Upon investigating the genitalia, I was greatly surprised to find a complete occlusion of the vaginal outlet and canal; however, at the upper commissure I found a pin-like opening, from which there dribbled a viscid substance. I attempted to introduce a very small probe, but owing to severe pain produced thereby, I forewent further procedure, and stated to the parent the seat of the nerve trouble lay here. Operation was readily assented to. The labia minora had disappeared entirely, or rather they were not distinguishable. The outer lips, however, were very much atrophied and irregular.

The operation performed was rather unique, and I have been unable to find anything advised like it. Separating the inner lips with a curved blunt-pointed bistoury, that I might introduce a pair of scissors, I slit the tissue down to the posterior fourchet. With dull dissection, practised with my index finger, I broke up what adhesion existed down to the vault of the canal. Cutting away the tissue of the labia minora, and trimming it smoothly, I inverted the labia majora as far down in the cavity as they would reach, and stitched them to the lateral walls of the canal, the attachment being practically at the bottom of the vaginal outlet. An uninterrupted catgut suture was employed on both sides. I next packed the entire canal with a sterile tampon of wool, anointed with carbolized vaselin, which was held in position by a large wad of sterile gauze and a T-bandage tightly drawn up and against the parts. I especially made no provision for passing the urine, as I felt this could do no harm in the face of the complete inunction which I gave the parts prior to the outer toilet.

The wound was dressed every other day for nine days, precisely as above. On the eleventh day I examined the parts thoroughly, and, much to my delight, no adhesions existed; no pain was experienced upon inserting the finger, and, all in all, the little girl is progressing nicely.

In regard to the growth of hair to be expected, I do not believe this will be a matter of much moment, for if we stop to study the anatomy of the surrounding parts, the growth of hair is practically confined to the upper and outer edge of the labia majora. I look also for some gradual stretching of the parts as the child grows older, and the tendency will be, in my opinion, upward and outward. The clitoris, which was somewhat obscured beforehand was detached, and is now perfectly free, with a natural hood. The child, from late reports, has had no return of the spasms, and the operation was done nearly three months ago. While a great many authors do not lay much stress upon an adherent clitoris causing nerve derangement in children, it certainly appears to me it did so in this case.

It might be added that the operation did not cause very much shortening, as regards the depth of the vaginal route.

The secretion from Bartholini's glands at times causes some irritation, but this can always be relieved by a hot douche.

Epistaxis in the New-born.—D'Astros writes in the *Archives de Médecine des Enfants* concerning the literature upon this subject, and concludes that it is on all occasions symptomatic of systemic infection. Hereditary syphilis, either accompanied by local nasal lesions or not, being the most frequent cause. The etiological factor in some instances is a septic infection, while frequently there is both syphilis and sepsis. In obscure cases careful examination may still reveal signs of latent syphilis. So-called idiopathic cases rarely, if ever, occur. The amount of the hemorrhage is not usually large, nor is it dangerous. The underlying cause constitutes the danger, and treatment should be directed toward its removal as early as possible.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 11, 1902:

	Cases.	Deaths
Measles	45	..
Diphtheria and croup	252	25
Scarlet fever	85	7
Smallpox	1	1
Varicella	23	..
Tuberculosis	210	149
Typhoid fever	138	29
Cerebrospinal meningitis	..	4

Bacillus of Shiga in Relation to Dysentery.—Contract Surgeon Charles F. Craig, Director of the Bacteriological Laboratory, U. S. General Hospital, Presidio, San Francisco, Cal., speaks thus of bacillus of Shiga in his report of last year: "I have continued my observations upon a bacillus separated from the intestine at autopsy in cases of dysentery, and it has proven to be the same as that discovered by Shiga in Japan, and studied very carefully by Flexner and Strong in Manila. This bacillus has proven to be the cause of the acute specific dysentery prevalent in Japan and the Philippines. Cultural peculiarities and the morphology of the organism has been so fully described by the observers quoted that I shall not enter into a description here. I have devoted the most of my attention to the agglutination test, and to the effect of the bacillus upon animals. As regards the latter, I may say that the results have been so contradictory that I have been unable to draw any positive conclusion from them. It has been found that this bacillus, which much resembles that of typhoid, will agglutinate when placed in the blood serum of a patient suffering from certain forms of dysentery, designated as an acute specific dysentery. Using the same method as is used for the Widal test and substituting this bacillus, I have tested the blood serum of seventy cases of dysentery. In making the test I have used a dilution of 1 to 10, and have allowed a time limit of fifteen minutes. The cases tested were all diagnosed as chronic dysentery, and of the seventy cases twenty showed the amœbæ in the fæces, and were, therefore, amœbic dysentery: (1) Of the twenty amœbic cases only one gave a reaction, which was very slight. This case came to autopsy, and was found to be a typical case of amœbic dysentery. It was impossible to ascertain whether or not the patient had previously had an attack of the specific variety. (2) Of the fifty remaining cases twenty-one gave a positive reaction and twenty-nine negative. Of the positive cases five came to autopsy, and the pathological conditions present were those of severe diphtheritic dysentery, the ulcerations were very superficial in character, and the entire large intestine was lined with a thin necrotic membrane covering the ulcerations. As a result of these examinations, I am inclined to believe that the agglutination test of Shiga's bacillus is comparable in accuracy with the Widal test. Perhaps this conclusion is a little premature, but the fact that the bacillus does not react in cases of amœbic dysentery is very significant."

Water Is a Thermo-Regulator.—The *American Review of Reviews* for September quotes largely from an article on the functions of water in the human body by Professor Karl B. Hofmann, which first appeared in the *Deutsche Revue.* A highly important function of water, says the professor, is that of regulating the temperature of the body, cooling it by evaporation from lungs and skin, and by perspiration. Bodily comfort depends on this regulation. Persons who do not perspire easily suffer more from heat. An increase over the normal temperature of

98 per cent. cannot be endured for any length of time. In high fever the bodily heat becomes unbearable on account of the disturbed regulation, and relief is experienced on perspiration. "We should appreciate the economic importance of water more," the writer concludes, "if it cost as much as the food we prepared in it." It is fully appreciated only by the traveler in the desert, who must carry it along for himself and his animal.

Blood-Letting in Gynecological Cases.—Bedford Fenwick has employed this form of treatment in more than a thousand cases. His conclusions are: (1) That when the cervix uteri is rendered by disease congested, deep-red bluish, or purple in color, local depletion by scarification generally gives immediate relief (2) When this congestion is caused and kept up by flexion of the uterus obstructing the return of the venous blood from the cervix and causing chronic enlargement of the uterine veins generally, local depletion allows a pessary to be inserted with safety and comfort to replace the organ, which almost certainly could not otherwise be tolerated. (3) The possibility of the patient being pregnant must, of course, be investigated before scarification is accomplished. (4) In cases of subacute ovaritis, or obscure throbbing pain in the pelvis, cupping or leeching externally frequently gives immediate relief. (5) In cases of vaginismus from inflamed hemorrhoids or other rectal congestive conditions, leeches around the anus give rapid relief or cure. (6) Scarification is the simplest and safest method of abstracting blood from the cervix.—*The Medical Times and Hospital Gazette.*

An Endeavor to Estimate the Value of Certain Doubtful Lives for Life Assurance.—F. Le M. Grasset thus sums up his study of the subject: (1) If a man has strong evidence of arteriosclerosis in his family history, and also in his person, he is not insurable on any terms; (2) If there is no family history of the disease, but if he has it in important organs like the brain, the kidney, or the heart, he is an undesirable risk, and most companies would do well to leave him alone, or to take him on some short endowment only, depending on the gravity of the lesion found; (3) If arteriosclerosis is shown markedly in the family history, but no evidence is present in the applicant by a rigid examination, an endowment terminating before or about the period in which this proclivity is most shown, might be offered, but not a whole life; (4) If the family tendency seems weak, or possibly even moderate in the direction of arteriosclerosis, but the personal examination is good, perhaps a life policy paid up in ten, fifteen, or twenty years might be offered, but before doing so, special care should be exercised in each case.—*The Medical Examiner and Practitioner.*

On Recrudescence of Inveterate Latent Syphilis after Acute Febrile Disorders.—Heinrich Oppenheimer says that it is a well-known fact that under the influence of weakening factors of any kind relapses are very liable to recur. But his experience has convinced him that febrile disorders are more frequently than other causes instrumental in imparting fresh activity to syphilitic residues in the system which have been in a dormant condition for many years. These unexpected manifestations do not break out on the height of the fever, but belong to the stage of convalescence, and to the period immediately following the latter, when the patient, to all external appearances, is quite well again. Cases of a mild and abortive type seem to suffer most frequently in this peculiar way, probably on account of the insufficient and unsatisfactory treatment with which they are too often content.—*The Clinical Journal.*

Recovery of a Needle Which Had Entered Patient's Body Many Years Before.—A. Mansfield Holmes reports the case of a patient who, from pain in the lungs, with slight hemorrhages, was suspected of tuberculosis. The tuberculin test gave no reaction. The patient was seized with excruciating pain in the pelvic region, which continued for several hours. A large fragment of a sewing needle was passed per vaginum with the menstrual flow, after which all pain ceased. Two weeks later the patient was seized with a paroxysm of coughing, which removed a solid mass, within which she found the remainder of the needle embedded. The two parts of the needle fitted perfectly. After the removal of both fragments all symptoms rapidly disappeared, and the patient has enjoyed excellent health ever since. She remembered having swallowed a needle about six years previously.—*The Colorado Medical Journal.*

The Press and Crime.—The suggestion has been made several times of late that the press is responsible for much of the crime that is apparently so prevalent nowadays, and it seems that it may contain the elements of truth. Dr. Icard, a distinguished French physician, is convinced that the yellow journals of France have had much to do with recent crime. He declares that women are especially apt to follow a certain kind of pernicious example. The French physician is strongly in favor of a law being passed making the publication of certain police cases illegal. The article of Dr. Icard, which appeared in the second April number of the *Nouvelle Revue,* is a well-written impugnment of the worst features of modern yellow journalism.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending October 11, 1902:

SMALLPOX—UNITED STATES.		CASES.	DEATHS
Colorado, Denver	Sept. 20–27	3	..
Illinois, Chicago	Sept. 27–Oct. 4	3	..
Kentucky, Covington	Sept. 20–Oct. 4	11	..
Maryland, Baltimore	Sept. 27–Oct. 4	..	1
Massachusetts, Boston	Sept. 27–Oct. 4	10	3

THE URINE FROM EACH KIDNEY.

By FERD. C. VALENTINE, M.D.,
NEW YORK.

CORRESPONDING MEMBER SOCIÉTÉ FRANÇAISE D'UROLOGIE; SECRETARY AMERICAN UROLOGICAL ASSOCIATION; SECRETARY GENITOURINARY SECTION, NEW YORK ACADEMY OF MEDICINE; ETC.

THE value of obtaining separately the urine from each kidney, is now too thoroughly appreciated to merit discussion. The manner of securing this most important aid to definite diagnosis is, however, still undecided. Ureteral catheterism, indisputably best, has its limitations, and also a goodly number of opponents.

Harris' and Downes' methods at first glance seem to overcome the difficulty. As, however, both are dependent upon the production of a "watershed" within the bladder, their applicability is essentially for the female. Although inexperience may cause an unfair criticism, it is risked by offering that Kelly's and Pawlik's methods appear easier, safer, and more effective for the purpose.

To obtain the urines separately from each kidney in the male, none of the methods hitherto employed can be effective, except ureteral catheterism by the Nitze, Casper, or Albarrán cystoscopes, or some of their modifications. These, however, require a bladder which has a capacity of at least 50 c.c., which is not bleeding, or into which one or the other kidney is not pouring blood too rapidly for the irrigating cystoscope to wash away; bladder walls which are not desquamating large shreds, ureters large enough to admit, at least, the smallest catheter, and other conditions evident upon a moment's thought. Moreover, ureteral catheterism demands continual practice, the greatest possible skill, acute vision, and most delicate manipulative tact.

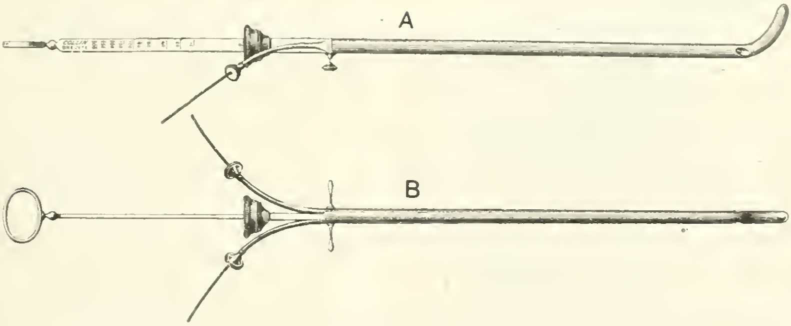
The purpose of this paper is to describe an instrument which at present seems to overcome all the difficulties that ordinarily attend efforts to obtain the urines separately from each kidney.

The instrument, in its present form, is due to Fernand Cathelin, adjunct chief of clinic at the famous Necker Hospital of Paris. It is to this most competent follower of our great master, Guyon, that I am indebted, not only for instruction in the use of his instrument, but also for the privilege of employing it, in the large material at his disposal.

Cathelin enjoyed the signal distinction of having his instrument presented before the Paris Academy of Medicine by Professor Guyon, on May 20, 1902. In his first publication[*] Cathelin attributes the originality of the idea of intravesical separation of the urines from each kidney to Alfred Neumann of Gruben. Neumann's instrument, however, entails insertion of a finger into the vagina to make the same water-shed which Harris and Downes accomplish by means of an intravaginal lever.

Cathelin's divisor is based upon pushing into the bladder a soft rubber membrane, which adapts itself to the walls, and which is grasped by the bladder, thus dividing the viscus into two halves.

In a subsequent article[†] Cathelin found that the originality of making two compartments of the bladder is due to Lambotte of Brussels, whose instrument was constructed in 1890[‡]. As, however, Lambotte's instrument was offered to the profession only as an experimental device, time need not be consumed now in discussing it.



FIGS. 1 and 2.—Cathelin's Vesical Divisor, closed. A. Lateral view B. Seen from above

Cathelin's graduated vesical divisor consists of a cylindrical tube (caliber 25 F.), shaped at one end like a short-beaked catheter. Figures 1 and 2 show the instrument laterally and from the top. Its distal extremity has a central orifice and two lateral catheter-carriers, each of the three closing with a screw-nut with washers, to prevent the escape of urine otherwise than through the catheters when the instrument is in use. The central orifice allows the easy propulsion of a shaft whose handle is graduated to the varying vesical capacities from 10 grams (ounce) to 300 gr. (f ℥ x). The two lateral catheter-carriers transmit each a catheter.

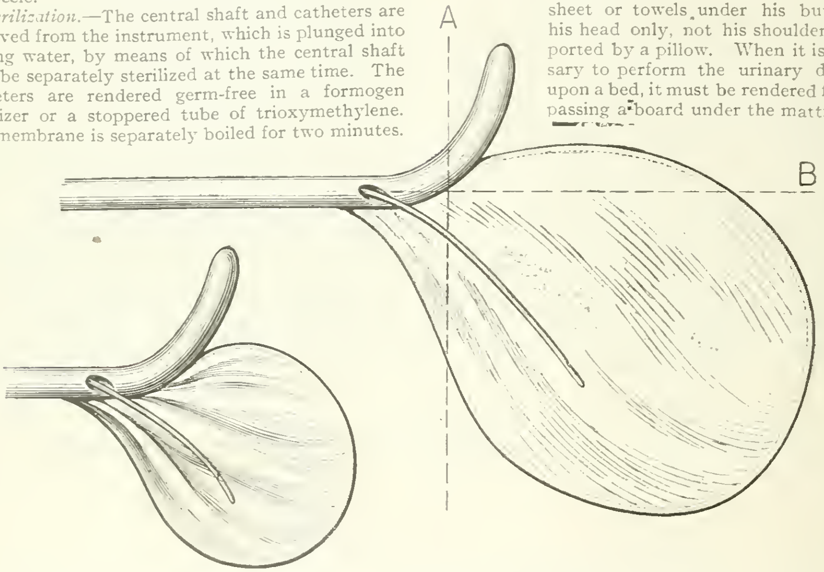
[†] Cathelin: "Les urines des deux veins."—*Annales des Maladies des Organs Génito-urinaires*, July, 1902.

[‡] Lambotte, in *Annales de Médecine et de Chirurgie du Cercle d' Etudes Médicales de Bruxelles*, p. 47, 1891.

The other essential part of the instrument is a very soft rubber membrane, set within a delicate steel spring. This membrane and the other parts of the instrument will be more minutely described when detailing the employment of the divisor.

The intravesical end of the divisor is guttered so that when the membrane is projected within the bladder it cannot otherwise than maintain a vertical position. It thus invariably centrally divides the bladder and the end of the posterior urethra into two parts. This fact enabled the author to obtain the urine from each kidney separately in a case of cystocele.

Sterilization.—The central shaft and catheters are removed from the instrument, which is plunged into boiling water, by means of which the central shaft may be separately sterilized at the same time. The catheters are rendered germ-free in a formogen sterilizer or a stoppered tube of trioxymethylene. The membrane is separately boiled for two minutes.



Figs. 3 and 4.—Intravesical part of Cathelin's Divisor. The larger figure shows the membrane expanded in a bladder of 300 grams capacity; the smaller one in 40 grams. Line A bisects the "neck of the bladder"; B the central line of the instrument. It is seen that the division extends to the posterior urethra.

Mounting must naturally be done with sterilized hands. The steps are as follows:

1. Open the screw-nuts of the catheter-carriers and insert into each a catheter; close the catheter-carriers just enough to permit their easily sliding through and beyond the lateral eyes of the instrument. Inject sterile water through the catheters to prove their permeability. These catheters are then withdrawn until their first gilded mark is at the screw-nut, leaving the other marks outside the tube; this places the catheter-tips just within the eyes of the main tube.

2. Insert the central shaft until its tip projects from the central tube. Fasten it there by means of the screw at the bottom of the tube (see Fig. 1). The projecting part of the shaft has a small spring; open this with a finger-nail and insert therein the stem of the membrane, pushing it in as far as possible. Release the spring and it will firmly grasp the stem. The membrane has neither top nor bottom; therefore, the only care necessary is to see that it is placed vertically in the median line (Fig. 3, B) of the instrument.

3. Dip the beak of the instrument, with the membrane attached, into a vessel at least four inches in diameter, and eight inches deep, containing sterilized olive oil.

4. Draw back the central shaft until it has carried the entire membrane into the tube, *i. e.* when zero on the graduation of the shaft is at its nut. It is well to project and withdraw the membrane several times, holding the tip of the instrument with the left hand and pressing the left index finger upon the lower margin of its orifice, as the membrane comes from and returns to the tube.

5. Fasten the retaining screw at the bottom of the tube and place the whole instrument into the vessel containing the sterilized oil (*vide* 3 above).

6. The cover of the box containing the instrument and its accessories has a support with two lyres (see Fig. 5). The upper lyre is for use in the male; the lower one is for female patients. Screw the support into the hole provided in the lid of the box.

Preparation of the Patient—1. He should lie preferably upon an operating table, a folded sheet or towels under his buttocks; his head only, not his shoulders, supported by a pillow. When it is necessary to perform the urinary division upon a bed, it must be rendered firm by passing a board under the mattress, to prevent its sagging, and to maintain the body in the horizontal posture.

2. Wipe the prepuce, glans, coronary sulcus, and meatus with cotton tampons soaked in mercuric bichloride 1-6,000; wash the urethra with warm boric acid 4 per cent., either by means of an irrigator or a syringe.

3. Irrigate the bladder with boric solution until the fluid that comes therefrom is entirely clear.

4. Measure the vesical capacity by very slowly injecting through a catheter, with a Guyon or Albarrán vesical syringe. When the first, slight desire to urinate is experienced, the minimal vesical capacity, as Cathelin calls it, is reached; when the desire becomes imperious, the same author designates it the maximal vesical capacity.

5. Allow the fluid to escape and inject 10 grams fresh solution, which will aid in establishing syphonage when the instrument is inserted, and save the need of aspiration, which is but exceptionally required.

The final injection is unnecessary in a polyuric patient; when the bladder is irritable, however, a larger injection than 10 grams will be required.

6. Introduce the instrument in the same manner as a lithotrite is inserted. In case the patient has a resistant urethra, it will be well to leave a retention-catheter *in situ* over night, or, at all events, for several hours preceding the division.

7. Hold the instrument in an almost horizontal

position and project the catheters according to the vesical capacity, previously ascertained (*vide* 4 *supra*), *i. e.* for a bladder holding 100 grams, insert the catheters to the second mark on the catheters; for a bladder able to hold 250 grams, push the catheters to the fourth mark, etc. Then close their screw-nuts to render them water-tight.

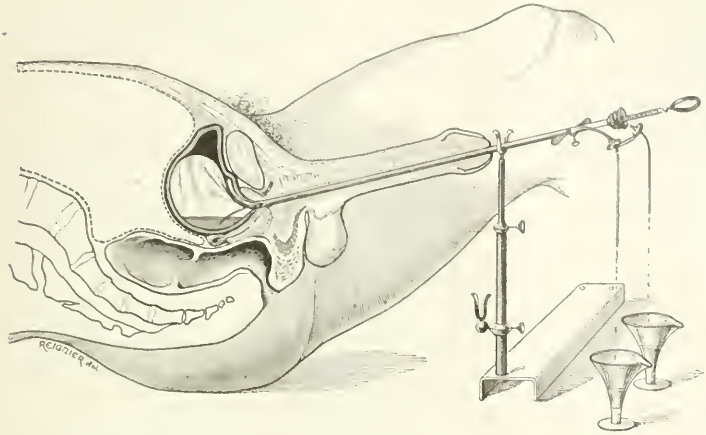


Fig. 5.—Cathelin's intravesical divisor *in situ*. The light intravesical part is the soft rubber septum, dividing the bladder into two chambers; the catheter is shown projecting into the right chamber, close to the ureteral opening, automatically syphoning the urine therefrom.

8. The bladder contents soon begin to drop from the mouths of the catheters; then draw the instrument horizontally outward until its beak is arrested by the posterior aspect of the pubis.

9. Release the fixing screw at the bottom of the instrument (see Fig. 1), and gently, slowly push the central shaft inward until the index thereon shows that it has penetrated to the bladder's minimal capacity, or a trifle less. Tighten the fixing-screw, to hold the shaft firmly.

10. Raise the instrument a trifle above the horizontal, and fix it in the movable lyre, which is attached to the upright that has been screwed into the lid of the instrument's case. This lid rests upon the table in front of the patient's buttocks (Fig. 5).

Notes on the Instrument. — When the membrane is projected from the central tube, it assumes an elliptical form; the posterior bladder-wall, however, gives it a spherical form, and fits it to all the normal and such pathological irregularities as the viscus may have. (See Figs. 5 and 6.)

Before attempting to collect any of the urine which comes from the catheters, the 10 grams of fluid that were injected before the instrument was inserted should be allowed to escape. To be sure that the specimens taken for examination are not mixed with boric acid, it may be well to exceed Cathelin's instructions and allow 20 grams of fluid to escape before collecting the specimens.

The urine then coming from the catheters may be received in clean glass dishes or test-tubes, or graduates placed beneath the mouths of the catheters. When the instrument is acting, it should not in any manner be disturbed, lest the relations between it sparts be disarranged.

If, however, urine ceases to flow from one side, Guyon's instillation syringe may be gently used as an aspirator, or several drops of water injected through the catheter which does not act.

Should the above-mentioned measures fail, the inactive catheter may be withdrawn and a new one inserted in its place, without removing the apparatus.

Removal of the Instrument. — When sufficient urine from each kidney has been obtained, the instrument is closed in the following manner:

1. Release the screw-nuts which close the catheter-carriers and withdraw the catheters.

2. Release the fixing-screw at the bottom of the tube and draw out the shaft until its marking shows O (zero) at its orifice.

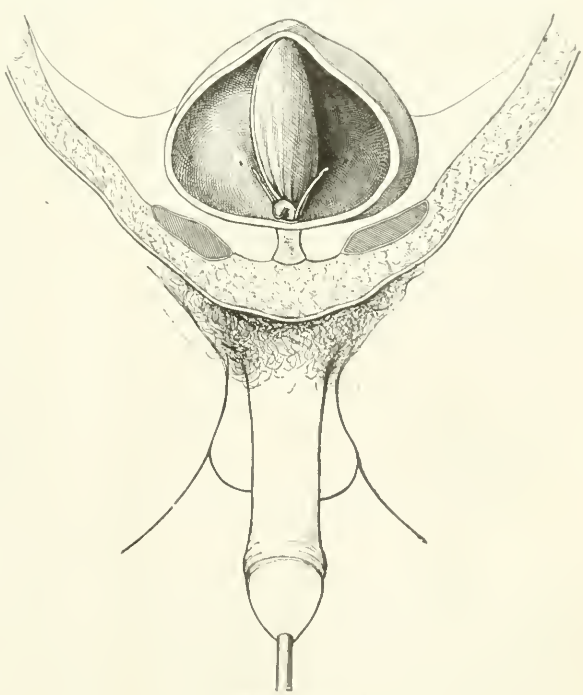

Fig. 6.—The membrane dividing the bladder into two compartments; each of the two catheters in its respective chamber.

3. Remove the entire instrument in the same way that any other rigid instrument is withdrawn from the bladder.

4. Wash the bladder with warm boric-acid solution, 4 per cent.

To Cleanse the Instrument.—1. Rinse the entire divisor in warm water.

2. Release the membrane in the same manner as it was fastened to the shaft.

3. Unscrew the caps of the catheter-carriers and force water through them.

4. Wash the membrane with soap and water; then with warm water, and dry it by pressing it between flat pieces of gauze. It is well to not employ a membrane more than once, but to cover the event of an emergency, it will be well to save membranes that have not suffered any injury from previous use. All membranes should be kept well powdered with finely pulverized talc.

5. The channel for the central shaft may be cleansed by repeatedly pushing cotton through it with the shaft itself.

Practical Applications.—The clinical manifestations in pyæmia or hæmaturia, in the majority of cases, suffice to give very fair presumption regarding the source of the pus or blood. The epithelia found microscopically in the urine serve almost infallibly to establish whether the pus or blood comes from the bladder or the kidney.* But neither the symptoms nor the microscope are able to show whether the blood or pus comes from the right or left kidney. Cystoscopy and ureteral catheterism, when possible, will establish this. But when, as in a large number of cases, not even cystoscopy can be performed, the divisor outlined fully, subserves the purpose, without a dangerous exploratory operation.

Facility of Employment.—That this divisor can be successfully employed by a person without extraordinary manipulative dexterity is shown by the fact that, after seeing Cathelin demonstrate it in five cases, I found no difficulty whatever in its use. In the past ten days I have obtained the urine separately from each kidney in eight patients. In each case I secured more than enough urine for chemical and microscopical diagnosis. In four of the patients the disease was located in the bladder. The largest bladder (female) which I examined had a capacity of 650 c.c.; the smallest was in a male whose maximal vesical capacity was 55 c.c. In this case there was the additional difficulty that the patient was unable to flex his left leg, because of ankylosis of the thigh and knee. Of the other cases, the right kidney was found diseased once and the left in the remaining three.

Of the patients mentioned three were females and five males.

The average time required for obtaining these urines was, in my inexperienced hands, as follows:

Mounting the instrument	2 minutes.
Preparing the patient	3 "
Obtaining sufficient urine from each kidney	10 "

No cocaine or other anæsthetic was employed in any of the cases. Two of these had irritable bladders.

Pain.—Of the eight cases, roughly noted, five had not been examined before. These five include the two with irritable bladders. None of them complained of more than the ordinary discomfort which is experienced on inserting an instrument into the bladder. One went to sleep about two minutes after the instrument was inserted. None of the patients experienced any discomfort after the use of the divisor.

Deeming, even after the little observation and experience mentioned herein, that Cathelin has opened the way to an effective, safe method, one that is also within the reach of the general practitioner, I submit this rough outline of the instrument.

31 West Sixty-first Street.

*Heitzmann: "Microscopic Urinalysis." Wm. Wood & Co., New York.

THE MOST FREQUENT FORM OF VAGINAL HERNIA; ITS ETIOLOGY AND TREATMENT.

By SAMUEL WYLLIS BANDLER, M.D.,
NEW YORK.

ADJUNCT-GYNECOLOGIST TO THE BETH ISRAEL HOSPITAL, NEW YORK
FORMER ASSISTANT AND OPERATOR IN THE CLINIC DÜHRSSEN, BERLIN.

While they do not constitute affections menacing the life of the patient, vaginal herniæ, especially the two common forms, are often associated with annoying symptoms, conditions, and states. Their origin, prophylaxis, importance, and treatment are not subjects of general agreement. Dependent as they are on the injuries and lesions consequent on labor, and evidencing their presence, as a rule, long after the same, various views as to the origin of certain vaginal herniæ have been based on the presence of uterine displacements and evident lacerations, while theories of an uncertain character have served to settle the etiology of other forms.

The connection between perineal lacerations and rectocele, for instance, is generally discussed without due attention to the important muscular lesions which produce this affection. Therefore, the frequency with which decided perineal lacerations are not accompanied by rectocele must have been noted by all close observers. For a long period the value of the perineum and the relation of its injuries to the condition known as cystocele have also been erroneously estimated. Most striking, from a clinical aspect, is the disproportion between the evident affection and the symptoms in numerous cases. External evidences afford no criterion as to the state of the deeper tissues of the pelvis or as to the annoyance the patient feels or may feel later on. The so frequent correction of these external herniæ without the attention to the real injury; the correction of uterine malpositions without preliminary or subsequent treatment of the other pelvic states which may not be characterized by digitally evident lesions, are therefore not always attended with satisfactory results.

The term *prolapsus vaginæ* is used to cover numerous pathological conditions affecting the wall of the vagina, and, as a consequence, its entity, as a distinct affection, is often hazily understood. An interrelation between prolapsus vaginæ, in its generally used sense, and displacements of the uterus is considered by many to exist. Küstner believes that the uterus cannot leave the pelvis or the vagina if situated in physiological anteflexion. He considers that it must first come into a position in which its axis has almost the same direction as that of the vagina. A retroversion or retroflexion then permits abdominal pressure to cause a descensus of varying degrees. The nearer the portio approaches the vulva, the more is the vaginal canal shortened, and so finally lies outside the vulva as a prolapsus vaginæ, a condition so often combined with a retroversio-flexio. He thus considers prolapsus of the uterus and vagina to result from the retroversio-flexio.

Any pronounced descent of the uterus is accompanied by a descent of the vault of the vagina, but it is impossible, however, to understand why, if a causal relation exists, the lower end of the vagina should so often protrude with a descensus uteri.

Although the presence of a retroflexion may make the origin of a prolapse of the vagina easier, yet Veit considers prolapse of the vagina an independent affection, and considers the vaginal wall to be the factor which pulls the uterus out of its normal position. Against this latter view it may be said that anatomical considerations and surgical experience prove that the parametria, when normal, are of such a character that a prolapse of the vagina is, of itself, incapable of pulling down or displacing the uterus.

Descensus uteri or hysteroptosis, and prolapse of the vagina, though often combined, are two independent affections. The fact that the two are so often co-existent, is no proof that one is the result of the other. Each, however, may occur independently and is due to the same cause, *i. e.* injury during labor and subinvolution. Atrophy or degeneration of certain tissues about the vagina may cause the mucous membrane to lie in folds, as is so frequently the case at climacterium, when there is a resorption of fat and a change in the connective tissues, a disappearance of active elastic fibers, and a loosening of the various relations. Such changes not infrequently occur, too, in younger women. In addition there is a frequent congenital malformation, whereby the lower end of the vagina, the hymen, and the external genitalia, extend beyond the rami of the pubis, constituting a congenital elongation of the vagina. This form, mild in nulliparæ, and often greatly increased in multiparæ, must be distinguished from true prolapsus vaginæ.

Just as hysteroptosis and prolapsus vaginæ should be, in a causal way, considered affections independent of each other,although their etiology is the same, so prolapsus vaginæ and the various forms of vaginal hernia should be differently viewed. The name cystocele is generally applied to any protrusion of the mucous membrane of the anterior vaginal wall extending through the external opening of the vagina, and which is either externally visible or which actually extends beyond the external genitalia. Such a condition, however, may be a congenital elongation of the vagina, a prolapsus vaginæ, or a true cystocele, A close distinction is rarely made, and the two latter terms are usually applied indiscriminately.

Prolapsus vaginæ and cystocele must be distinguished, for a cystocele constitutes simply a hernia of the bladder, as may be seen from a study of the anatomical conditions. Cystocele, too, is independent in its origin of uterine displacements. I am reminded of a recent case of decided cystocele, in a woman fifty-five years old, which had pulled down the anterior vaginal fornix and the vaginal covering of the anterior wall of the cervix, so that this area, too, was a part of the cystocele covering. Tension had elongated the anterior lip of the cervix at least one inch, and yet the uterus was in normal position and not descended. On the upper portion of the cystocele wall intestines could be felt, for the bladder connections with the cervix were entirely loosened. No rectocele was present and no descent of the posterior or lateral vaginal walls.

We may have (1) Cystocele with a normally situated uterus; (2) Cystocele with a hysteroptosis; (3) Cystocele with a retrodeviated uterus; (4) Cystocele with a hysteroptosis plus a retrodeviation of the uterus. In addition we may have cystocele with or without rectocele.

The diaphram of the pelvis is formed of the levator ani and the musculus coccygeus and is perforated by the rectum, the vagina, and the urethra. The rectum is the only one of these three canals really united to the levator ani.

A muscular connection for the urethra and the vagina begins only when they pass through the trigonum urogenitale.

The vagina at its outlet is surrounded by the musculus bulbocavernosus, which is attached posteriorly to the centrum perineale, and which anteriorly surrounds the corpus clitoridis. It is called the constrictor cunni. The pars anterior of the musculus trigoni urogenitalis is situated at the sides of the vagina, its fibers crossing anteriorly in front of the urethra, forming the compressor urethræ. The pars media of the muscle consists of circular fibers arranged about the vagina and the urethra. Higher up the fibers do not unite behind the vagina, but do unite about the urethra alone.

The vagina penetrates the diaphram of the pelvis in the middle of its own length. On its upper surface is the vesicovaginal septum of connective tissue and its close connection with the urethra, the urethrovaginal septum. Laterally, it is bounded by a a vessel plexus and connective tissue, and *by the levator ani.* Only at its lower end has it the above-mentioned intimate relations with muscle fibers. The important relations of the vagina are with the trigonum urogenitale and its muscle, the perineum, the septum urethrovaginale, *and especially with the levator ani.*

The urethra in its lower two thirds is firmly connected with the vagina. Laterally, on either side, passes the levator ani. Lateral to it and surrounding it are the musculus trigoni urogenitalis and the musculus bulbocavernosus. Anterior to the urethra are the plexus venosus pudendalis and the trigonum urogenitale.

The bladder in the newly born is a tube narrowed above into the urachus, which, with the umbilical arteries, holds the bladder close to the anterior abdominal wall. In adults, after descent of the bladder, spaces are formed, which are filled with fat. Before puberty the fundus of the bladder rests upon the cervix, and the upper third of the vagina. In adults only the trigonum vesicæ rest on the vagina and possibly upon the portio. Because of the absence of the prostate, the orificium internum urethræ lies deeper than in the male. Below the bladder are the symphysis, a body of fat, the pudendal plexus, and the urethra. Below and lateral to the bladder are the connective tissues of the parametrium and the muscles of the pelvic floor, *especially the levator ani.* In front of the bladder is found the fascia vesicæ, and the cavum Retzii filled with fat, in front of which is the transversalis fascia covering the posterior surface of the symphysis.

The bladder is held in place by the peritoneum, the fascia vesicæ, the ligamenta umbilicalia, the musculi pubovesicales, and the ligamenta pubovesicalia. It is supported by the vesicovaginal septum of connective tissue, connective tissue, fat, *and the levator ani muscle.* From a study of these relations (Waldeyer), it may be seen that the vagina, except at its outer end, is simply surrounded by connective tissue. The only thing which prevents the vagina from being pushed down by abdominal pressure is the *action of the levator ani muscle* and the character of its connection with the surrounding connective tissues. Atrophy or degeneration of these tissues cause the mucous membrane of the vagina to lie in folds, as is so frequently the case at climacterium, and in younger women, too, when there is a resorption of fat, a change of connective tissues, a disappearance of active elastic fibers, and a loosening of the various relations. Such a condition affects the lateral wall of the vagina, primarily, to only a slight extent. It is only affected secondarily after prolapse of the anterior wall.

After pregnancy and labor there is a disturbance in the anatomical condition of the various structures of the pelvis. The levator ani and constrictor cunni are decidedly stretched and often torn, and, as a result, the narrow vagina is widened, and the original narrow slit becomes a large canal. There is a disappearance of fat, and a flabbiness and œdema of the connective tissues and of the ligaments—that is, subinvolution is observed. Such a condition in the anterior wall, almost always a sequence of labor, permits the filled bladder, *loosened from its fastenings*, to descend and produce a dilatation of the weakened anterior vaginal wall *through the injured levator ani and the connective tissue floor*, which, normally, keeps it in place. The lesions are exactly the same as occur in hernia in the linea alba of the abdominal wall.

This tendency to flabbiness of the connective tissues is a frequent result of labor, and occurs most frequently in individuals who exhibit this tendency as nulliparæ. Gastroptosis, gastroenteroptosis, and ren mobilis have been found to occur frequently in rhachitic and neurasthenic individuals. I have referred to such cases evidencing as nulliparæ a decided tendency to a descent of the uterus and to flabbiness of the pelvic structures, and have referred to the frequency of their combination with abdominal ptoses. To this descent of the uterus, of whatever grade, because of its etiology, I have given, in harmony with the conditions existing in the abdomen, the name hysteroptosis. These patients especially, as well as others, show after labor every evidence of subinvolution, even if the uterus return to its normal size. The ligaments of the pelvis and of the abdomen are loose, œdematous, and flabby, and the muscles of the pelvic floor evidence the same characteristics. Most important, there has been an injury to the levator ani and the musculus trigoni urogenitalis, or else these muscles are subinvoluted. Naturally enough, as a result of the descent of the uterus, or as a congenital condition, retroflexioversio is frequently present, and for this reason main attention has been paid to the displacement, and it has been considered the etiological factor in causing the subsequent changes, while the element of local and constitutional subinvolution and predisposition to flabbiness has been overlooked.

With such cases, as well as with any other case of subinvolution of the pelvic structures, if there has been a stretching of the levator ani or a rupture of the same, a space is immediately formed which furnishes opportunity for descent of the bladder through pressure upon the weak, anterior vaginal wall. The œdematous swelling of the urethral prominence and its protrusion into the vagina are the first evidences. Added to this, the same conditions of œdema exist in all the connective tissue elements uniting the bladder with the abdominal wall, with consequent loss of their support. The erect position, abdominal pressure in emptying the bladder and in defecation, plus the abdominal condition, result eventually in a descent and hernia of the bladder. Perineal laceration with the supposed resulting absence of support of the anterior vaginal wall by the posterior wall has nothing to do with this resulting hernia.

In catheterizing, in these cases of true cystocele, it is perfectly evident that the bladder fills out the dilatation in the anterior wall, and the bladder no longer rests on the levator ani of the two sides, which, normally, are close together along the urethra and the lower portion of the vaginal wall. In cystoscoping these cases it is readily seen that the bladder constitutes a hernia. It is not the descent of the vaginal wall which brings the bladder with it, but the weight of the filled bladder which dilates and stretches the subinvoluted anterior vaginal wall. I have, in numerous instances, found the uterus absolutely normal in situation and pulled down into the vagina only with difficulty, and yet the cystocele was pronounced.

Proof of the fact that the weight of the filled bladder is the cause is shown by the frequent recurrence of a cystocele after anterior colporrhaphy, even though, in addition, a high perineum is restored by plastic operation with a resulting narrow vaginal canal.

Out of the broad general class, prolapsus vaginæ, we must remove the following forms of *vaginal hernia:* (1) The most frequent, involving the lower half of the anterior vaginal wall, the so-called prolapsus vaginæ anterioris, or, better and truly speaking in most cases, *cystocele.* (2) Prolapse of the upper third of the anterior vaginal wall through descent of the intestines (rare). It is only possible when the union between cervix and bladder has been disturbed. This condition constitutes an *enterocele vaginæ anterioris.* (3) Prolapse of the upper portion of the posterior vaginal wall through a descent of the intestines, or *enterocele vaginæ posterioris.* Here the uterus and the lower half of the vagina are not affected as regards their position. The upper part of the posterior vaginal wall, however, is influenced by the intestines in the sac of Douglas. (4) A so-called prolapse or dilatation of the lower half of the posterior vaginal wall containing a diverticle of the rectum—a *rectocele.*

The various forms are usually combined. The lateral walls are rarely affected. In those conditions in which the uterus is normally elevated, in conjunction with these affections there may be an elongatio colli, extending even to the vulva. Primary hypertrophy of the collum is rare. It results usually through tugging on the part of the bladder and vaginal wall. The collum is usually very thin and atrophic, and is due either to atrophy after inflammation or to atrophy due to the above tugging, and occurs only when uterus is originally fixed.

In line with the fact that the etiology of acquired retroflexioversio is an hysteroptosis, it is found that the most frequently noted form is *cystocele with descensus uteri.* Next in frequency is *cystocele,* plus *rectocele.* The latter is due to laceration of the perineum and to injury to the perineal and rectal insertion of the levator ani. Least frequent, supposedly, is *cystocele alone.* My experience, however, shows this last form, existing alone, to be much more frequent than generally stated. A prolapse of the uterus with invagination of the vagina usually occurs only after the climacterium, as a result of senile atrophy of the pelvic tissue.

Even with shortening of the round ligaments, or ventral fixation a cystocele frequently recurs after anterior colporrhaphy. Two factors may be stated as a certainty: (1) The cure of a retroflexion is not necessary to a cure of the cystocele. (2) Treatment of the posterior wall is not necessary to correct the lesion in the anterior wall. Theilhaber treated, surgically, twenty-four patients, almost all of whom showed an elongatio-colli. The anterior colporrhaphy consisted in making the excision extend far, laterally, into healthy tissue. He resected the anterior vaginal wall up to the lateral wall, paying little or no attention to the posterior vaginal wall or to the perineum. Out of twenty-four patients thus treated twenty-two remained without recurrence, the other cases could not be traced. There were no recurrences, in spite of the fact that fifteen cases had retroflexed uteri which were not treated.

The good results obtained by Theilhaber were due (1) to so changing the character of the anterior vaginal wall that the upper ends of the levator ani muscle were brought closely together, (2) to narrowing the vagina, and (3) to removing the thin urethrovaginal septum and so closing the space on the under surface of the bladder, through which this organ formerly descended.

Another valuable method, and one which is of considerable importance, is the *vaginofixation* of the uterus according to the method of Dührssen. Although its value in the case of women past the child-bearing period is generally acknowledged, this favorable opinion as to its worth in younger women is not general. Without going into the question further, suffice it to say that the experience of my teacher, Dührssen, since the perfection of his method and my own experience in thirty cases, leaves no room for criticism. (1) It corrects the uterine displacement; (2) It does not interfere with the normal completion of pregnancy, and the normal process of labor. When done for the correction of a uterine displacement, the purpose of this operation is to attach the fundus of the uterus to the anterior vaginal wall. When, in addition to the main purpose the correction of a cystocele is desired, and likewise when done mainly for the correction of a cystocele, the fundus of the uterus is attached to a lower portion of the anterior vaginal wall, and forms an artificial base on which the bladder rests, and entirely separates the bladder from the anterior vaginal wall. This operation, devised and perfected by Dührssen after various modifications, if correctly done, avoids, theoretically and practically, the posibility of future annoyance.

The vaginal mucosa on the anterior wall of the cervix is incised transversely about three-fourths of an inch above the external os. The upper margin of the incised vaginal mucosa is grasped by forceps, and its connective tissue connection with the cervical muscularis is separated by scissors, after which the finger dissects bluntly between the bladder and the cervix and uterus, up to the reflexion of the vesical peritoneum upon the anterior surface of the uterus. With a knife or with scissors, a longitudinal incision is made along the anterior vaginal wall at right angles to the original transverse cut, which procedure should be done with care, for the bladder lies closely upon the vaginal mucosa. The two flaps thus formed at the union of the longitudinal incision with the transverse incision are everted, and, with the scissors, the connection between the bladder and these two vaginal flaps is separated, and the longitudinal incision may be extended even up close to the outer opening of the urethra. A retractor is introduced between the bladder and the uterus, and the vesicouterine fold of peritoneum is grasped and incised at the median line of the uterus. With forceps, or clamps, the margins of this incision are grasped, and a longitudinal incision is made in the peritoneum, extending up to its connection with the bladder. This connection with the bladder is loosened by blunt dissection, which is easily accomplished, and the longitudinal incision in the peritoneum is exextended still further, until it is at least three to four inches long. The retractor is then introduced through this incision into the peritoneal cavity, and the volsellum, which has held the cervix during these steps, is used to push the cervix down and back, which tends to bring the fundus of the uterus forward into view. If the uterus be adherent, or if it does not come forward, a volsellum is applied to the lower portion of the uterus and traction is exerted. Another volsellum is then applied further up on the uterus, and another still further, if necessary, until the fundus of the uterus is brought through the peritoneal longitudinal incision into the vagina, when the tubes and ovaries may be delivered and brought into view.

The next step consists in attaching the uterus in the desired position. The two aforementioned anterior vaginal flaps may be resected to any degree which is considered advisable, after which two silkworm-gut sutures are applied as follows: On the left side the needle is passed through the left margin of the longitudinal vaginal incision as far anteriorly as it may be desired to finally bring the fundus uteri. It is then passed through the left upper margin of the longitudinal incision in the vesicouterine fold of peritoneum. It is then passed through the uterus at any desired point, passing deeply through its anterior wall, preferably a little below the level of the Fallopian tubes. It is then passed through the right upper margin of the longitudinal incision in the vesicouterine peritoneum and through the right margin of the longitudinal anterior vaginal incision, at a point directly opposite the entrance of the suture. Following the same course a cat-gut ligature or another silkworm-gut suture is passed one-half to one inch above the first on the vaginal wall, passing, of course, the same distance further down through the anterior surface of the uterus. The uterus is then pushed back into the peritoneal cavity and the *incision in the vesicouterine fold of peritoneum is closed with a running cat-gut suture.* Traction is exerted on the two original sutures, and the longitudinal and the transverse incisions in the vaginal wall are carefully closed with running cat-gut sutures, after which the two silkworm-gut sutures are tied carefully but firmly, bringing the uterus into the desired position, and are left in place from four to six weeks. In older women past the child-bearing period, the procedure is the same except that the incision in the vesicouterine peritoneum is not closed, which brings the anterior surface of uterus into contact with the vaginal wall itself, and causes a very firm attachment. It was this procedure, with the consequent close union to the anterior vaginal wall, which caused, in the early days of this operative procedure, disturbances during labor. When, however, the peritoneum is closed the union resulting is formed between the peritoneally-covered anterior uterine wall and the vesicouterine peritoneum, which latter, in turn, is closely united to the anterior vaginal wall. The resulting union is then one between the peritoneal surface of the uterus and the vesicouterine peritoneum, which is the same histological result as is obtained in ventral suspension.

127 East Sixty-first Street.

A Motor Way through England.—A writer in the *Nineteenth Century and After* suggests that a special cycle way should be constructed, as direct as possible, from London, through the center of England, as far as Carlisle, from which it could be continued to Glasgow or Edinburgh, if not to Inverness. The surface of the cycle, or motor-car way to be formed by means of specially hard creosoted wood blocks, with asphalt joints. Compared with a railway, the cost of permanent way construction would be trifling. The question of gradients, embankments, bridges, tunnels, and curves is comparatively trivial, because although this motor-car or cycle way would probably be used for freight traffic, the light weight of such cars, compared to a locomotive and railway train, would permit a very light form of bridge construction to be used. The writer is of opinion that a small annual fee of thirty cents from all the members of the cycle unions and clubs in Great Britain would go a long way toward financially justifying the construction of such a cycle way." The idea seems a good one, and its consummation would, doubtless, be hailed by the majority of the British public with feelings of satisfaction and relief. Something of the same sort should be undertaken here, where motor-car drivers have altogether too much license.

ON THE ERADICATION OF YELLOW FEVER IN HAVANA.

By EDMOND SOUCHON, M.D.,
NEW ORLEANS, LA.
PRESIDENT OF THE LOUISIANA STATE BOARD OF HEALTH.

We read in the Medical Record of July 19, page 81, an article by Dr. W. C. Gorgas on "Mosquito Work in Havana," in which he claims that yellow fever has been eradicated from Havana, and that through the destruction of mosquitos. It is here assumed that yellow fever has been truly eradicated in Havana, and that all cases are truly reported.

No one admires more than I do the great efforts and the splendid results obtained by Dr. Gorgas in the sanitation of Havana, but as a seeker of truth for truth's sake, and regardless of its consequences, it has occurred to me that, although the destruction of the mosquito may have prevented the spread of yellow fever in Havana, the real cause of the *present exemption* of Havana and of the island from yellow fever is due truly to the efficient quarantine work of the United States Public Health and Marine Hospital Service officers. They kept out the fever and, therefore, prevented the spread of it by mosquitos or any other cause. The past history of New Orleans bears out this view. Up to the time of the incipiency of scientific quarantine, from 1879 to 1884, there was yellow fever in New Orleans every year, more or less, because the quarantine methods employed up to that time permitted the constant introduction of cases by vessels without ever giving the city a chance of exhausting one infection before another infection occurred. Since the inauguration of thorough disinfection of vessels, especially since 1884, under the vigorous championship of our Dr. Joseph Holt, the city has been practically free from yellow fever until the infection of 1897, through the Mississippi coast. It took three years for this infection to exhaust itself, and New Orleans is again free from yellow fever. All that was accomplished without any precautions whatever having been taken against mosquitos.

Now it is my firm belief that the same thing has taken place in Havana, through the agency of a perfect quarantine, which has prevented the annual infection of the city and gave the infection a chance to exhaust itself. This view is corroborated by the fact that at the ports of Mantanzas, Nuevitas, Cienfuegos, and Santiago, where the officers of the United States Public Health and Marine Hospital Service kept up a rigid quarantine since the occupation of the island, no yellow fever has developed *this year* any more than in Havana, and yet no *serious* crusade was undertaken at these places against the mosquitos.

In a letter to Professor Chaille, published in the *Tulane Phagocyte* of August, 1902, Lieut.-Col. V. Havard says: "The report that there was no mosquito warfare in Mantanzas, Cienfuegos, and other large towns in 1901 is a very serious error. Special orders were issued for the destruction of mosquitos in all garrison towns. . . . Port surgeons had to report monthly to what extent the existing instructions had been carried out in their respective towns, and with what success."

It is not probable that much was accomplished, as the following information tends to prove: Upon writing for information on this subject to the Surgeon-General of the Army, the following reply was received from Major Walter Reed: "I do not know whether any systematic destruction of mosquitos was carried on in any Cuban port other than Havana."

In a letter, Dr. Glennan says: "I do not understand that any systematic effort has been made to exterminate the mosquitos in other Cuban ports outside of Havana."

Dr. von Ezdorf, from Matanzas, writes: "Upon inquiring of the Health Officer of Matanzas the petroleum used in the city over vaults and cesspools in 1901 did not suffice to cause the entire disappearance of mosquitos in Matanzas."

Dr. Wilson writes from Santiago de Cuba: "During the winter of 1900 and 1901 a systematic house-to-house inspection of the whole city and the immediate suburbs was made, noting the condition of privies, sinks and drains, etc., and pouring crude petroleum in these places and wherever else water was likely to become stagnant. . . . The result was an evident *diminution* of the number of mosquitos in the city *for quite a while*. . . . Since the Americans have left the island nothing has been done to kill the mosquitos."

Surgeon-General Wyman informs me that: "At Cienfuegos the medical officer states that no campaign for the destruction of the mosquitos in that vicinity, before or since May 20, 1902, has been carried on."

Dr. McConnell of Nuevitas, Cuba, replies: "No campaign leading to the destruction of mosquitos has been carried on at this port during 1900 and 1901."

I do not wish to be understood that I believe the work of eliminating mosquitos useless, because I do believe that it *hastened the exhausting of the infection*, but I do believe that Havana would have become free of yellow fever anyhow, and that the *actual exemption* is truly due to the quarantine work that prevented the introduction of new infection.

The following is a list of the epidemics of yellow fever in New Orleans from 1817 to 1899 inclusive—eighty-three years:

YEAR	DEATHS	YEAR	DEATHS	YEAR	DEATHS
1817	809	1845	2	1873	226
1818	115	1846	160	1874	11
1819	2,190	1847	2,359	1875	61
1820	400	1848	808	1876	42
1821	...	1849	769	1877	1
1822	239	1850	109	1878	4,046
1823	1	1851	17	1879	19
1824	108	1852	456	1880	2
1825	49	1853	7,970	1881	0
1826	5	1854	2,423	1882	1
1827	109	1855	2,670	1883	4
1828	130	1856	74	1884	1
1829	215	1857	199	1885	..
1830	117	1858	4,855	1886	..
1831	2	1859	91	1887	..
1832	18	1860	15	1888	..
1833	210	1861	..	1889	..
1834	95	1862	2	1890	..
1835	284	1863	2	1891	..
1836	5	1864	6	1892	..
1837	442	1865	1	1893	..
1838	17	1866	192	1894	..
1839	452	1867	3,107	1895	..
1840	3	1868	5	1896	..
1841	594	1869	3	1897	297
1842	211	1870	588	1898	57
1843	487	1871	55	1899	23
1844	148	1872	40		

I hold that yellow fever in a locality exhausts itself in from two to four years, provided fresh cases, especially virulent ones, are not brought in from the outside, although the material, *i. e.* non-immunes, be still present in the locality.

By studying the foregoing table it will be found that: The infection practically exhausted itself in one year in the years 1822, 1837, 1839, and 1873. The infection practically exhausted itself in two years in 1824 and 1825, 1875 and 1876, 1878 and 1879. The infection practically exhausted itself in three years in the years 1866, 1867, and 1868; in 1870, 1871, and 1872. The infection practically exhausted itself in four years in 1817, 1818, 1819, and 1820; in 1827, 1828, 1829, and 1830; in 1832 1833, 1834, and 1835; in 1857, 1858, 1859, and 1860. The infection practically exhausted itself in five years in the years 1852, 1853, 1854, 1855, and 1856. The infection practically exhausted itself in six years in the years 1846 to 1851.

Therefore, four infections exhausted themselves in one year, three in two years, two in three years, four in four years, one in five years, and one in six years.

Although fresh cases were introduced almost every year reinfection took place only when specially virulent cases were imported.

I do not believe that it would be safe to do away with all quarantine restrictions and rely solely upon the destruction of mosquitos in a port to prevent that port from becoming infected. There have been mosquitos in Havana this summer, I know from private information received, and if no cases of yellow fever occurred it is because the efficient quarantine has kept yellow fever out.

If the contentions of Dr. Gorgas are correct, all quarantines should be cast away and reliance placed on the destruction of the mosquitos. That is what some of our brethren from infected ports say to us of the infectible territory; destroy your mosquitos, so that if you get a case of yellow fever from us it will not spread. It would cost much less than quarantines, since Dr. Gorgas states that it costs only $7,000 to destroy the mosquitos in Havana. But we cannot see it that way.

This is written in no carping spirit of opposition, but is simply an effort to establish the real truth. I have waited patiently for some one to reply to these statements and to analyze the facts. No one has replied. I do so reluctantly, but I cannot allow to pass statements upon which may be based quarantine regulations which may prove disastrous.

I reassert here my thorough belief in the transmission of yellow fever by mosquitos, as demonstrated by the memorable labors of Dr. Walter Reed, his co-workers and followers, but I believe, from practical facts before me, that there is some other means of transmission.

Until these facts are satisfactorily explained and demonstrated to us, we, of the Louisiana State Board of Health, the guardians of the health of the city of New Orleans, the State of Louisiana and of the whole Mississippi Valley, cannot think of altering the present maritime quarantine regulations.

This, be it understood, is an expression only of my personal views in the matter.

Excision of the Knee for Chronic Rheumatism.—Theodore A. McGraw says that if he is consulted by a patient who has an incurable rheumatic affection confined to one knee, and who has no other serious trouble, such as Bright's disease, or general tuberculosis, he does not hesitate to advise resection of the knee-joint. The operation, if properly done, on an otherwise healthy subject, has extremely little danger, and the bones will usually heal by first intention. The patient will rejoice in unwonted freedom from pain, and in about three months in the return of a long-lost ability to use his leg in walking. There will be but a slight limp, and the only great inconvenience experienced will be the projection of the stiff leg when sitting. From a chronic invalid, depending upon external support, he will be transformed into an independent, well, and active man. The author reports three cases, all differing from one another.—*The Hot Springs Medical Journal.*

SOME EARLY STAGES OF THE DISEASE OF INEBRIETY.

By T. D. CROTHERS, M D.,
HARTFORD, CONN.
SUPERINTENDENT WALNUT LODGE HOSPITAL, ETC.

The inebriate rarely, if ever, comes under medical care until he has reached a chronic stage of the disease. He is considered, in this anterior period, willful and wicked, and treated by moral suasion, the pledge, and prayer, and perhaps punished by law, and all without relief. At last he comes to the asylum and under medical care. Five, ten, or fifteen years of the toxic use of alcohol have gone by, the patient is a continuous or a periodic inebriate, has had many attacks of delirium tremens; he has tried every moral means and failed, and yet his faith in his ability to stop at will is unshaken. He comes to the asylum, in his own estimation, not from any inability to abstain on his part, but for some minor affection, and to gratify others who misapprehend his case. Thus, at the start, he gives evidences of mental derangement. When his case is studied, most decided marks of both physical and mental degeneration appear. Congestions, and disturbances of liver, heart, stomach, skin, and other organs, and alterations of the higher functions, noted in changed character, conduct, notions, disposition, and emotions are clearly apparent. The pronounced character of these symptoms of degeneration, with the history of their duration, point to a chronic stage that is present. When these symptoms are noted and carefully grouped, they become the point from which the course of the disease can be traced backward to its origin. Notwithstanding the difficulties of a search down through a realm where every event or phase was supposed to come from wickedness, the great number and variety of acts that point to a regular order of progress and distinct stages in the case show clearly that inebriety, like all other diseases, follows a progressive line of dissolution from a certain origin and development down to chronicity and death. My purpose is to trace some of these early stages of inebriety, show that they can be seen, and preventives and curative measures, applied at this time, give more promise of certain results than at any other period.

It will be understood by all who have any experience in these cases that heredity is the largest and most prominent factor in the causation—an heredity that dates back to inebriate, insane, idiotic, epileptic, or consumptive parents—an entailment of degeneration that is likely to develop into any one of these diseases, depending upon some unknown determining cause; also that inebriety is surely one of this family group, and likely to come from or merge into any one of them. In a study of cases of inebriety, running back into the earliest incipient stages, many and very prominent symptoms appear which may be put down as pathognomonic, and may be divided into two groups: one noted before any spirits are used; the other coming on after alcohol has been used. These are only outline divisions, and point to periods that may extend over years, or be limited to a few weeks. The first may be termed the pre-alcoholic stage, and the second the post-alcoholic period. Probably the latter stage is more prominent, and yet both are psychological and pathological periods that have never been studied from this point of view before. It should be remembered that in nearly all of these cases a pronounced heredity is present. In these stages a number of prominent symptoms appear, and increase up to a certain point where inebriety is recognized, then they change and are lost in other and more distinct signs of progressive degeneration. Thus a child at puberty, or later at full manhood, will develop an unstable brain and nerve organism easily exhausted, associated with a capricious appetite for foods and drinks. This will go on increasing with varied and complex neurasthenic states then inebriety will manifest itself unmistakably and rapidly pass into chronic stages. Or these symptoms of brain instability and food delusions and derangements may appear in previously healthy men, following illness, injury, or mental shock, such as sorrow, grief, loss, and suffering. Some illustrative cases will bring out this phase more clearly:

A man with a marked heredity, both insane and alcoholic, early in his business career began to manifest a strange appetite for unnatural foods, such as decayed meats and large quantities of strongly acid water. He would use one article of food to surfeit, then turn to another. He became very emotional and changeable in manner and disposition. This period of great eccentricities of conduct and use of food and drinks suddenly merged into pronounced inebriety two years later. The food delusions vanished, but other and most prominent signs of mental failure followed. He is now, ten years later, a low, chronic inebriate.

B—— had a doubtful ancestry; showed soon after puberty an unusual liking for rich foods. He would spend all the money he could get to buy rare delicacies in the market; was also very vain of his looks and person; would not drink any form of spirits, but used tea and coffee to excess. His mind was unsettled and full of changing fancies and notions about himself and future. He drank to excess soon after graduating from college, and is now a chronic inebriate in an asylum.

C——, with an epileptic parentage, developed the same food eccentricities at about twenty years of age. He had dyspepsia and showed a mania for taking pills, and was full of delusions as to the effects of foods and drinks on his body. He drank large quantities of water both night and day, and finally became an inebriate.

Each of these cases was thought not to be peculiar, except in their judgment of foods and drinks. They were noted for emotional exaltation and depression, dyspepsia, etc., but this was supposed to follow their excesses, and to be of no general importance.

Another class is, in my opinion, more common. The following are illustrations:

A——, a good business man, who was temperate and apparently well up to forty years of age, suddenly believed that he could indefinitely prolong his life by the selection of foods and drinks. He gave this subject all his leisure time and thoughts, and was a monomaniac; soon emotional changes and conduct followed, and he drank to excess. His food mania disappeared and he became a periodical inebriate.

B——, a lawyer, temperate, well; at thirty used food to great excess, had an acute attack of dyspepsia. Then he ignored all solid food and lived on gruel and liquid foods in small quantities. From this time he imbibed many delusions, and his brain and body showed marks of debility. A physician ordered spirits as a remedy, and inebriety was the result. I have met with many cases of this kind, in which inebriety was preceded by similar delusions in men of apparent good health and vigor, and which soon merged into either alcoholic or opium inebriety. In these cases no particular cause was traceable to account for these delusions and alterations of brain function.

Another class is noted in which these symptoms follow some distinct cause, and end in the same way, as in the following:

A——, with consumptive heredity, was a temperate, hard-working man up to thirty years of age, when he was greatly prostrated by the death of his child. After recovery he manifested great anxiety to find medicines that would relieve some undefined state of his body. He became very fastidious about the quality and character of food eaten. He went to the butcher and inspected all the meats purchased, and was very particular about the preparation of food and excitable if it was not done according to his will. He was very nervous about little things, and his disposition and temper changed. Finally he became a periodic inebriate, and is now serving out a term of imprisonment for assault committed during a drinking paroxysm.

B—— was a merchant, temperate, and well up to forty-five, when he suffered from concussion of the brain. A year afterward he developed dietetic delusions and lived on separate articles of food and special forms of drinks from plants and shrubs. His mind was changeable and he conceived that clothing was dangerous after it was worn a short time. He put on new suits every week, and was in a state of constant alarm for fear of disease from poison. He suddenly drank to intoxication, and became an inebriate at once.

C——, with insane ancestry, after an attack of typhoid fever was alarmed for fear of a return of the disease. He manifested various delusions of food and drink as a source of contamination from the poison of this disease. He ate to great excess one day, then abstained the next, sought all kinds of quack remedies, and finally drank to excess and was an inebriate.

A clergyman, after an attack of pleurisy, developed the same symptoms, principally dietetic and medical delusions, which ended in inebriety. An officer in the army, after a period of great suffering in prison, became an epicure, with delusions as to the quality and value of food and of the care of the body, which two years later developed into inebriety. A banker lost all his property, and soon after a morbid fear of death and desire to avert it by food and drinks possessed his mind, ending in inebriety.

In these and many other cases that I have seen, the history of the incipient stages showed these same mental disturbances in relation to foods and drinks. In some cases delusions with regard to the care of the body, and sudden impulsive ambitions to outstrip others in strength or grace or beauty; or morbid fears of death and delusions of specific medicines to prevent it. I have found this peculiar delusion as to the power of remedies, and the possibility of foods and drinks to perpetuate life and keep away disease, present in clergymen and literary men in many instances which ended in inebriety.

Morbid appetites and unusual tastes in youth and early manhood are very strong hints of inebriety, which may go on, or be checked by some unknown causes. The early history of many cases point to great mental activity before inebriety began, in addition to these food delusions that have been described. In one case a merchant who, from being a very quiet man, after the appearance of food delusions seemed to have delirium of work, which lasted over a year, then merged into inebriety. In another case an unusual desire to be noted was associated with his delirious food impulses. Thus the more accurately the early history of inebriates is traced, the clearer the evidence of a progressive order of symptoms appears before spirits are used, and the subject assumes a sudden enormous expansion, as this new realm of psychological forces is seen and comprehended.

In the second group, or post-alcoholic stage, the symptoms of inebriety after alcohol is used are recognized more generally. In this class the so-called moderate drinker is prominent. When he is studied carefully, his condition and symptoms are only found to vary from the chronic case in degree. The delusion of power to stop at will is noted in the chronic inebriate and the moderate drinker. A certain number of moderate drinkers continue in this state a life-time, and suppose it is owing to superior will power that they do not become chronic cases. Literally, it is the absence of some peculiar exciting cause. As, in smallpox, a certain number of cases who are exposed do not take the disease; a certain number of cases with symptoms of incipient phthisis never go on to full development, so the moderate drinkers who do not become inebriates are rare exceptions to the rule. Under all circumstances, the moderate drinker transmits to the next generation a weakness that is sure to appear as one of the allied neuroses. The symptoms of this stage of moderate drinking vary widely, but are all signs of change or breaking down. Delusions of foods and drinks, of strength, of superior character and judgment, with alterations of character, conduct, motives, and a steady failure of the higher brain functions, seen in little things, emotional changes, states of exaltation and depression, great pride in dress and surroundings, or the absence of it are common. In brief, the history of the moderate drinker reflects nearly all the various delusions and degenerations of the chronic inebriate The skilled psychologist can trace these in outline in this stage of the moderate use of spirits. In America this stage of moderate drinking is generally short, the slightest strain or drain on the nervous system precipitating the case into a chronic one, or death occurs from some intercurrent affection.

Another class of cases consists of those who have been profoundly intoxicated or poisoned by alcohol, then abstained for an indefinite time, and finally become inebriates. This period is full of hints and signs of oncoming inebriety. This class have a peculiar interest, because many very prominent temperance workers come from it, and not a few sensational preachers, lawyers, and literary men are found in this shadowy borderland of disease. When these cases come under observation, a new continent of psychological facts appears. The following are illustrations:

A——, a distinguished temperance lecturer, used alcohol to great excess for two years, then abstained for twelve years, becoming famous in the lecture field. He drank, and came under my care. From a study of the interval of sobriety it was found to be marked with symptoms of progressive degeneration, that of necessity would develop into inebriety or some one of the family group. Prominent was the almost sublime delusion in his strength to resist all temptation to use spirits again, with constantly increasing egotism and alternate activity and indolence. For days he would be plunged into the deepest depression unless on the lecture stand, where he would appear in the highest spirits and in a state of great mental exaltation. He was at times very avaricious, then generous, and all his conduct and character seemed to grow more uncertain, although his work on the lecture stand seemed much better. He was full of delusions of the care of his body, of food, of drinks, clothing and sleep, and steadily lost faith in the value of honesty or respect for his word. At times he would borrow oney and refuse to repay it. He recovered and went back to the lecture stand, but he was a chronic inebriate, with but little hope for the future. B——, a man of forty, drank to intoxication, continued in moderation for several months, and then abstained. Gradually he gave up his work (that of a merchant) and became a lay preacher. He exhibited great egotism and desire for notoriety, and would sacrifice everything for an opportunity to preach. His private life was full of petty selfishness and dishonest dealings, grasping, tyrannical, and changeable impulses. He ate and drank in the same erratic way. All this was foreign to his usual manner and conduct. He became an inebriate after an interval of sobriety lasting eight years, and remained so until death. In both these cases the first intoxication had started a train of defects that continued on through the free interval of sobriety, and could have been recognized by the medical examiner.

Another case illustrates a class of which I have seen several. A——, a physician, drank to excess at his graduation, then became an abstainer. He was conscious, from that time, of a great change in the control of his appetite for food and drink. He was very uncomfortable when hungry and thirsty—was irritable, nervous, and unreasonably excitable until this demand was satisfied. This grew more and more imperative, and he was very careful to eat with regularity, and thus save himself from these bad feelings. To his friends, he grew more irritable, and at intervals was very moody, dull, and bad-tempered, and ate voraciously, also using large quantities of tea and coffee. This lasted for six years. Then he had a paroxysm of drink, and soon became a periodical inebriate. The incipient stages in these cases cannot be mistaken, and the careful observer will find in many circles men of talent and often of prominence who have all the symptoms of approaching inebriety, or even inebriety itself, only they do not use spirits.

In the periodical inebriates and the irregular impulsive reasoning drinkers there are always many and varied symptoms which show the march of dissolution and the approach of the drink paroxysm with more or less certainty. Those engaged in treating inebriates can anticipate the return of the drink craving by symptoms that are fixed and unchanging. So expert do they become in certain classes as to be able, days in advance, to predict the drink storm. This study of early symptoms in inebriety must of necessity be only an outline, for the reason that the inquiry was begun in the fully-developed case and carried back to the early stages, depending on the memory of the patient and friends. When these statements were generally uniform and consistent with the later progress of the case, they were put on record as entitled to confidence. In this way outline forms of a distinct stage of inebriety have appeared, before unknown, except as a period of great wickedness. This incipient stage may be briefly noted as one in which the higher brain centers gradually lose the power of performing their higher and more complex functions. Varied forms and states of neurasthenia, with food delusions, produce exhaustion which opium or alcohol quickly relieves. The injury and change is in the brain centers in most cases, depending upon some inherited defect in cell growth or special diathesis, and starting into activity from unknown causes. Beginning long before alcohol is used, and accelerated into chronic stages by this drug, or kindled into activity by the first use of these narcotics, it becomes the disease of inebriety, characterized by an insane and maniacal impulse for relief from this nameless pain and agony of the degenerate nerve centers. Practically, the recognition of this incipient stage of inebriety opens up a field of possibilities for the cure and prevention, a fact of the greatest importance. As an illustration, the wild, impulsive, irritable boy, who seems to have no control of himself, and goes about almost lawless, that is sent to sea or to the army, workhouse or prison, and comes back later a chronic drunkard, might have been saved if the medical man had been called in, and recognized in these symptoms of approaching inebriety. The young man just entering business or a profession, who has eccentricities of diet, clothing, or conduct, which excite ridicule and ostracize him from the sympathy and friendship of others, becomes an inebriate. Had these symptoms been recognized, and had he been placed under treatment, this would have been prevented. Or take a more common illustration: The over-worked business and professional man, who finds all his previous habits, character, and motives changing, who has dietary delusions, and who is recommended bitters and spirits by the non-expert physician, and soon after finds that he cannot stop the use of stimulants and is an inebriate: or the still more dangerous practice of traveling abroad in the wine countries of Europe by men who have all these symptoms of nerve and brain degeneration, with nutrient disturbance of both mind and body, the result of which, in most cases, is the development of inebriety in the most decidedly chronic stages.

The advice to travel is often fatal to this rapidly-increasing class of sufferers. All these cases should come under careful examination by the physician, the heredity and mental and psychical hints of the present should be studied as carefully as the state of the heart or the nutrition of the body. The history points out stages where the prevention and cure would have been an easy matter; but later, when they come to the asylum, a degree of degeneration has come on in which little can be done that will prove permanent. To one who studies these cases carefully, comes the most profound conviction of a disease present which, following a regular order of progress from its origin to the termination, can be seen and traced by the symptoms. Stages of beginning and progress will be observed when medical skill and art are potent and available for cure and restoration, and later, stages where little can be done except to house the patient and keep him from injuring others. To call attention to this early incipient stage of inebriety, to explore and map out its boundaries, is the pioneer work in the great unexplored "dark continent" for scientific men of to-day. In this first study of the early stages of inebriety I have sought to make prominent the following facts:

1. The study of inebriety reveals a well-marked disease, passing through various stages, traceable by many and complex signs and symptoms.

2. The incipient stage seen before spirits are used is marked by dietetic delusions and other symptoms of nerve and brain irritability, all of which seem to depend on heredity or some obscure injury to the nerve and brain centers.

3. A group of symptoms can be found in most cases that may be termed pathognomonic, and will be seen in the later stages fully developed.

4. These early symptoms appear after the first toxic use of alcohol, and in some cases go on to full development, or are held in abeyance by some unknown force.

5. Practically, the recognition and study of this stage opens up a field of prevention and cure that will attract great attention at an early day.

THE X-RAY.

By MILTON FRANKLIN M.D.,
NEW YORK.

A Geissler tube is a glass tube, hermetically sealed, and having fused into each end a platinum wire. Gases at different degrees of attenuation, within the tube, exhibit various phenomena when electrical discharges take place between the platinum wires within the tube. With a view toward the investigation of the phenomena of highly attenuated gases during the electrical discharge, Crookes designed a modification of the Geissler tube, in which the platinum wire ended on the one side in a square plate of platinum, and on the other in a slightly cupped aluminum plate mirror. In some of these tubes the wires ending in the platinum plates were increased in number to two or more. The tubes were exhausted to various degrees of pressure, in some cases an almost perfect vacuum being attained.

When an electrical discharge is passed through a Crookes' tube in which the exhaustion is as low as 2 mm., the negative pole is surrounded by a narrow layer, and then by a relatively dark-bluish layer, the rest of the tube being filled with layers of reddish-yellow light, separated by dark spaces; as the rarefaction proceeds, the bluish light extends and, under some circumstances, fills the whole tube. The light proceeds from the negative electrode to the positive. When the vacuum is almost complete, the nature of the phenomenon is greatly altered. The light now proceeds from the negative electrode in straight lines, and wherever it strikes the glass of the tube, it excites the most brilliant fluorescence. The dark region surrounding the negative pole is the scene of a most violent transport of molecules repelled from the negative electrode. The cathode may be so shaped and placed that the molecules, always traveling at right angles to its surface, are caused to fall on a definite position on the glass. This region of the tube is then illuminated with a great phosphorescent light. There has been a great deal of discussion during recent years as to whether this is really due to molecules traveling within the tube, or whether it may not be due to longitudinal vibrations within the ether. Crookes advanced the theory that there existed a fourth state of matter, or the ultra-gaseous state, which he calls radiant matter. Professor Röntgen, in working at the subject, discovered that the light from the phosphorescent area of the glass contained some form of radiation that possessed extraordinary properties. It traverses paper, wood, aluminum, but not most metals; it is not regularly reflected or refracted; objects are more or less opaque to it, according to their physical density; it makes fluorescent substances fluoresce; and it affects the photographic plate. If the hand or arm be placed between the light and a photographic plate, the rays will penetrate the soft parts quite readily, and the bones will offer more resistance, so that a shadow of the skeleton will be photographed on the plate.

What the nature of this radiation is, if radiation it be, is not yet clear; some think it due to an actual permeation of the transparent body by molecules from the source of light; and others think it entirely a phenomenon of stress in the electric field.

With an increase of exhaustion, the potential necessary to cause a current to pass diminishes till a certain point is reached at which the pressure represents the exhaustion of least resistance; from this point, the exhaustion being continued, the resistance continues to increase till a point is reached at which the current cannot be made to pass at any obtainable potential. When the rarefaction has attained 0.002 mm. the current just passes even with a potential of 11,330 volts, while with an exhaustion of 0.000055 mm., the nearest approach to an absolute vacuum ever attained, it is impossible to produce a discharge even with a potential of 70,000 volts. The enormous potentials necessary to produce the discharges in the Crookes' tubes used in the production of the *x*-ray may be approximately estimated when we remember that it requires 70,000 volts to produce a spark of one inch in air, and that the length of spark is proportional to the square of the voltage. This is only approximately true, as there are other variable factors that enter into the calculation.

The source of electricity may be either a static machine or an induction coil. In the case of the static machine, the amount of current that the machine is capable of accumulating is proportional to the square of the area of the electrodes. From this it may be readily seen that the length of spark that a given machine can be made to produce is proportionate to the size of the electrodes. Thus, if the electrodes are capable of accumulating a sufficient charge to produce a spark of, say, two inches, then, no matter how much electricity is brought to that electrode, it will leak into the surrounding air when the charge on the electrode has reached the maximum. If a body at a lower potential be brought to within two inches of this charged electrode, the charge will escape over the intervening gap in the shape of a spark; and subsequently as quickly as the charge collected on the electrode has reached the point at which it is sufficient to produce the spark the phenomenon is repeated, and so on, *ad infinitum*. If, on the other hand, we increase the area of the electrode by placing it in electrical communication with the plates of a leyden battery, we will be able to get a much longer spark from the same source as before.

In the case of an induction coil, the length of spark depends directly upon the voltage in the secondary coil when the circuit in the primary coil is broken; for the alternate current in the secondary coil when the circuit in the primary is made is too feeble to penetrate the tube. This is not true for large coils, where we get an alternating discharge, and also where the coil is run upon an alternating current without an interrupter the discharge is equal in both directions. The difference in the effects produced by the coil on the one hand, and the static machine on the other, may be briefly stated as follows: In the former a spark is produced every time the primary circuit is interrupted; and in the latter a spark is produced every time enough electricity is accumulated to overcome the resistance in the circuit. Thus, in the coil, the number of sparks depends entirely on the number of interruptions in the primary circuit; in the static machine the rate of discharge depends on the rate at which the electricity is supplied to the electrode, the square of the area of the electrode, and the resistance in the circuit. Here we come upon an important consideration; for, whereas the rate of discharge in the case of a coil will be the same for any tube, it follows that the quantity of current passing in a tube of low resistance will be greater than in the case of a higher tube; but in the case of a static machine, the rate of discharge will regulate itself to the resistance of the particular tube that is placed in the circuit, and, therefore, the amount of current for a given tube will be constant at all times; the number of discharges increasing and the potential decreasing as the resistance in the circuit is lowered, where there is a constant rate of supply, and at no time will there be a greater difference of potential in the machine than just sufficient to overcome the resistance in the circuit. This difference in the conditions met with in the actions of the coils and static machines might account for the greater proneness of coils to produce burn, that some observers claim to have noted.

The measure of a tube is determined by its resistance as compared with air. Thus a tube that will require the same potential to penetrate it as will produce a spark of eight inches in air is called an eight-inch tube. There are some important differences in the tubes now used as compared with the original Crookes' tubes. The positive electrodes are now made of platinum, sometimes combined with iridium, and the cathode is arranged to propagate the rays at an angle to the anode or other target. Some tubes have two cathodes, with a view toward increasing the concentration of the rays in a given direction. Tubes are called high or low, according as they offer more or less resistance to the passage of the current; this is determined by the degree of exhaustion beyond the exhaustion of least resistance. It has been found that the high tube has the greater penetration, *i. e.* that it will penetrate substances of varying resistances with more uniformity, and therefore tends to level their densities. On the other hand, the low tube has the opposite effect, and tends to exaggerate the difference in intensity in the various substances traversed. Low tubes produce more burn than high tubes. The degree of attenuation of the medium within the tube determines the resistance, which might be so great as to render the tube impenetrable. Tubes are made in which the degree of vacuum may be varied within wide limits. In these tubes there is a small tube fused into the larger one and communicating with its inner space. This small tube is sealed at the outer end and contains a small quantity of caustic potash. The large tube is exhausted by means of a pump, whilst the small tube and its contents are kept red hot. When the greatest degree of exhaustion possible has been attained by the pump, the tube is sealed and the small tube allowed to cool. As the caustic potash cools it absorbs the last trace of moist vapor in the large tube and a high vacuum results therein. If at any time the vacuum in the tube becomes too high, the caustic potash is heated by means of a flame or current, whereupon it gives up some of its contained moist gas, causing the pressure in the tube to gradually rise till the spark can pass. If the pressure is increased to the point of least resistance, the discharge will be seen to take place in the shape of a thin, blue, luminous wave. The strength of action of the light from a tube varies inversely as the square of the distance of the tube from the object.

The manner in which the rays affect the tissues is a matter of vague speculation at the present time. Some think that the effect is produced by the projection of molecules into the tissues; some that it is electrical energy that is projected; some that the vibrations cause the tissue elements to oscillate in a cycle out of harmony with their regular molecular motion, thus causing a disintegration of the molecular structure; some that the *x*-ray produces the ultraviolet ray within the tissue by a process of interference; and finally, though probably not correctly, the action has been considered due to the setting free of ozone within the tissues by the rays.

The modern, and, at the present time, generally accepted theory is that the rays are composed of negatively charged corpuscles or electrons. A fact of some significance is that M. Goldstein has demonstrated that at the place where the rays impinge there is formed a thin layer of ultra-violet light.

Herr Schmidt holds that the cathode rays have a mark reducing power, and do not act by producing ultra-violet light, but more probably by saturating the electrolytic valency of the substance.

153 West 46th Street.

INFECTIOUS BRONCHOPNEUMONIA.

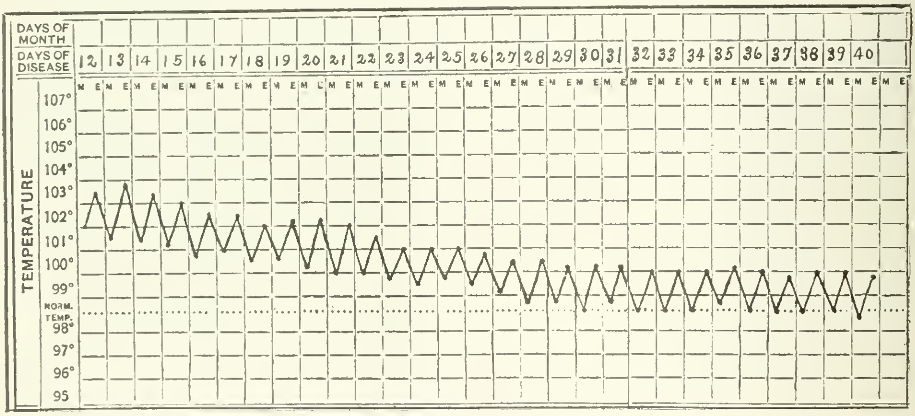
A REPORT OF SIX RECENT CASES.

By D. W. WYNKOOP, M.D.,
NEW YORK.
ATTENDING PHYSICIAN OF NORTHERN DISPENSARY.

During the last week of July I was called to attend two cases of illness occurring in children of nine and six years of age respectively. Their history elicited the following facts:

Up to the time of their illness they had enjoyed excellent health; previous to being at their country home (situated not far from Barnegat Bay), they had spent almost a month at Atlantic City; during this time, so far as the mother knew, they had not been exposed to any disease; she knew of no illness occurring in the hotel at which they stopped; the railroad journey from Atlantic City to their country place had been made in a Pullman car, of which they were the only occupants. The night of their return Case No. 1 (a girl of nine years) complained of being tired and chilly, and she was put to bed. The next morning an attack of vomiting and a cough were the only symptoms which presented themselves; vomiting subsided, but the cough increased in severity during the next few days, and with it a gradually increasing febrile condition. I saw Case No. 1 for the first time eight days after the onset of her illness. I found her sitting up in bed playing and, apparently, very cheerful, except for a dry cough, which hurt her. There was no suffusion of the conjunctiva or other sign of coryza present. My surprise was considerable when, on counting, I found her respirations 40, pulse 124, and temperature 103°.

The physical examination of her chest showed coarse and subcrepitant râles over both lungs in front and behind, and slight pleuritic friction râles over the apices of the left lung, and a diagnosis of bronchopneumonia was made at once.



Case No. 1

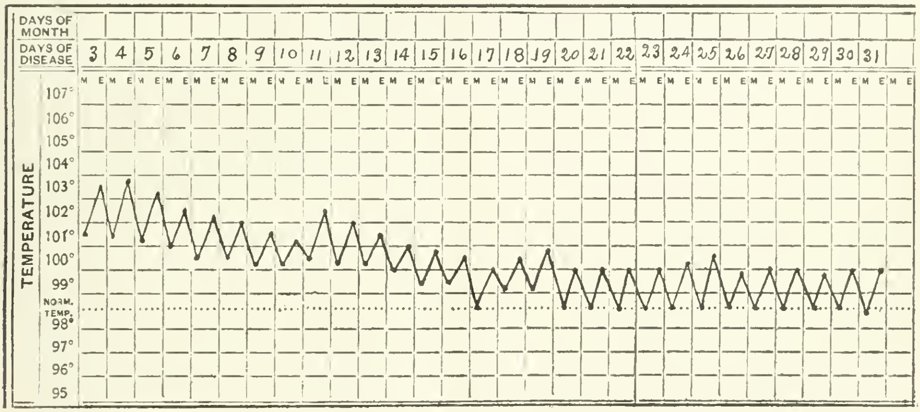
From Case No. 1 my attention was directed to the younger sister (Case No. 2), who, the mother told me, was "a little out of sorts," and had been for the last two days. On examination I found a temperature of 103°, pulse 130, and respiration 34. She also was in a cheerful mental state. The physical examination of her lungs showed a small central area of consolidation of left lung, and a diagnosis of pneumonia was made.

The similarity of the two cases at once suggested to my mind the likelihood of an infectious form of this disease, and I deemed it wiser to quarantine the two children at once, to prevent, if possible, the spreading of the disease to the rest of the family, and, in particular, to the youngest child, a little girl of three years. This was done, and two trained nurses were put at once on the case. The course of the disease in Cases Nos. 1 and 2 went its usual way (see charts of temperature). No. 1 proved much the more serious (at one time a fatal issue seemed imminent), but both finally gave way to treatment, and at the end of the third week the lungs of both cleared up and the cough ceased. Not so with the afternoon temperature, however. This seemed to have come to stay, but its alarming feature was discounted, as convalescence went on well and weight increased in both Nos. 1 and 2.

On the eighth day of August Case No. 3 came down—the youngest child, age three years. She began with a temperature of 103°, a severe laryngitis, and a very croupy cough. For two days the infection seemed to limit itself to this portion of the respiratory tract, but gradually it worked its way down till a general bronchopneumonia developed, which under early treatment ran a more rapid course, terminating favorably.

On the twentieth of August Case No. 4 came down, an adult of about twenty-eight years of age. She was one of the trained nurses in charge of the patients. The night previous she had gone to bed feeling very wretched. When I first saw her she spoke of having had a chill in the early morning, which had been followed by violent pains all over her body, but more particularly in her back. (This latter remained a constant factor for over a week.) There was slight nausea but no vomiting. Her voice was little above a whisper, though she did not complain of her throat being sore. The temperature at the onset was 102.6°, pulse 126, and respiration an irregular 40 to the minute. The physical examination of chest showed roughened breathing over both lungs, but no râles. These developed on the second day, with a tight and painful cough. By the end of the third day there was a general bronchitis, reaching down to its furthest extent in both lungs. As her case progressed, the chief difference between it and an ordinary bronchitis seemed to be in the impossibility of liquifying the cough. Under the administration of heroin the frequency of cough would be diminished, but the rest given to the inflamed tubes did not seem to render secretion any less tenacious. Her laryngitis continued for about a week, and it was ten days before the bronchitis subsided and the temperature fell to normal. For three weeks after the initial attack there was a slight afternoon rise of temperature. In Case No. 4 we had a clear enough history to point to an attack of influenza of the bronchial type. In Cases Nos. 1, 2, and 3, however, there was little to suggest anything except a very infectious form of microorganism at work destroying lung tissue. In all four cases quinine had been given in some form or other from the very start.

To this list of four cases I can add two others which I saw in consultation on Long Island this summer. One was in an adult and the other in a child of the same family. The case of the adult ended fatally. In both these cases the symptoms were the same as those of my Cases 1, 2, 3, and 4, even to the extent of having contracted the disease at Atlantic City. In these two latter cases I was fortunate enough to get blood examinations made, which showed, besides a diminution in number of red blood cells and hæmoglobin, a leucocytosis, and, scattered throughout the specimen, the bacillus characteristic to influenza came into view. The blood specimens were taken at the height of the afternoon temperature. The printed charts of Cases 1 and 2 served as a type for all.



Case No. 2.

Conclusions.—In looking back over these cases, which are at least out of the common, several thoughts formulate themselves in my mind. This disease is highly infectious in young children. The period of incubation is about twelve days (this deduction is made from Case No. 3). The attending physician would have little chance of making a correct diagnosis in a single case. In all cases there was an absence of coryza at the onset, and only in adults was the severe pain in the back spoken of. The disease in most cases gained its first apparent foothold in the larynx, and no amount of carbolized steam inhalations or quinine would alter its course a single degree. Without question it is systemic, with the bronchopneumonia its local manifestation. The prognosis is good, except when the case has been neglected and is in want of proper treatment. Proper treatment calls for the same care and local measures as would be used in an ordinary bronchopneumonia. Quinine seems to do little good, except as a stimulant. Its effect on the bacillus is apparently nil. In children we can look for an afternoon temperature for six weeks after the lungs have been cleared up and the cough has ceased. This temperature does not affect the general health, and they will even pick up the weight they have lost during the illness. Unlike ordinary influenzas, there is no mental depression following. In other words, you would not know they were ill unless you happened to take their temperatures at the right time.

Is it wise to send healthy children, or adults, for that matter, to a place which is known as a health resort? Is it not reasonable to expect that just such a thing would happen? The physician rushes his patient off at the first possible moment to his favorite health resort with the advice that they must stay out of doors as much as possible, and cheers them with assurances that the cough and afternoon temperature will gradually wear out. What is more natural for one who has been cooped up for weeks, or possibly months, to have yearnings for society, companionship—in other words, to join the throng on the "board walk"? They do it, and it is to be expected that while out on parade fits of coughing and sneezing will be easily induced by the gentle sea breezes.

In writing up these cases, I have striven more to produce a pen picture in simple language than a pyrotechnical display of medical enthusiasm. I trust the report will find its way into the hands of that lonely practitioner who, unaided, is groping his way against an afternoon temperature to which he can put no name which brings satisfaction to self.

Post-Graduate Course in Physical and Dietetic Methods of Treatment.—This course, inaugurated last year at Baden-Baden, Germany, proved so popular that it is to be repeated this year, commencing October 13. The course continues for about eight days.

Progress in Public Hygiene.—Dr. Samuel W. Abbott, the well-known sanitarian, published in the *Boston Medical and Surgical Journal*, at the beginning of May, a series of articles treating of the above subject.

The following data relative to the prevalence of smallpox, as determined by the mortality returns of different countries, are of interest:

Group I. German Empire.—The smallpox mortality of the German Empire is available for 1886 and the succeeding years. That of Prussia for the years 1880—1885 was considerably higher than that of the whole empire during the succeeding years. The highest smallpox mortality in the fourteen years of record was only 4.2 per million in 1886, and the lowest was .1 in 1897.

Scotland.—The highest death-rate from smallpox in Scotland in the 20 years was 31.5 per million living in 1894, and in two years, 1890 and 1891, there were no deaths from this cause.

Ireland.—The highest smallpox mortality in this country was 75 per million in 1880, and the next highest 31.8 in 1895, and in four years there were no deaths from this cause.

Sweden.—In Sweden the mean annual death rate from smallpox for the twenty years was 9.3 per million, but if the period is divided into two parts of ten years each, the death rate from smallpox in the first half was 18 per million or 15 times as great as that of the second half (1.2 per million).

Switzerland.—The death rate from smallpox has been exceedingly variable, ranging, during the nineteen years of record, from only .3 per million in 1895 and 1897 to 149 per million in 1885.

Holland.—Here, also, the range is extremely variable; there were no deaths from smallpox in 1899, but in 1883 there were 673, or 160 per million inhabitants.

England.—In England the smallpox mortality has varied from as low as .8 per million in 1897 to 119 per million in 1881, the mean for the whole period being 33.8 per million, and was the highest of this group.

Group II. Italy.—The figures of Italy include the thirteen years from 1887 to 1899, and show a high, but diminishing mortality from smallpox, the highest being that of 1888, or 612 per million, and the lowest 7 per million in 1899, the mean of the thirteen years being 179.

Japan.—In this country the extremes are still greater, ranging from as low as .6 per million in 1890, to 1,122 per million in 1882. In the year 1879, not included in the table, the death rate from smallpox was 3,060 per million, the total number of deaths from smallpox in that year being 113,228. The mean death rate from smallpox for the seventeen years of record was 201 per million, or, if 1879 is included, 347 per million.

Belgium.—In Belgium the highest death rate from smallpox in this period, 749 per million, was in 1880, and the lowest, 20 per million, occurred in 1896. Even this lowest rate was nearly five times as great as the highest rate of the adjoining country, Germany.

Austria.—During the nineteen years of record the mortality from smallpox ranged from 962 per million in 1882 to 36 in 1896.

British India.—In this country, with a mean population of about 216,000,000, during the 20-year period, 2,057,227 persons are known to have lost their lives from smallpox, and there was no single year in this period in which the deaths from this cause were less than 40,000. In the two single years, 1878 and 1879, preceding this period, the deaths from smallpox amounted to more than half a million (505,337), while those of 1883 and 1884 were still greater in number. Even in the best year of the period, the smallpox death rate was forty-three times as great as that of the highest year in Germany, and the mean mortality from smallpox (475 per million) was 264 times as great as that of Germany.

Hungary.—In Hungary the record is incomplete, but for the five years of record the mortality from smallpox ranged from 932 per million in 1887 to 69 in 1893, with a mean death rate from this cause for the ten years of 516 per million.

Spain.—In Spain the record is also incomplete. The smallpox death rate showed less variation than in any of the other countries. In no one of the years of record was it less than 285 per million, and the mean death rate from smallpox in these years was 605, or 336 times as great as that of Germany.

Russia, France and Denmark.—The published records of these countries are quite incomplete. Those of Russia, in Europe, for the six years, 1887—1892, show that 90,934 deaths from smallpox occurred in those years, which was equivalent to a death rate from this cause of 175 per million.

In France the records do not pertain to the whole country, but to the larger cities, and in these cities, with a population of about 9,750,000, there were 17,013 deaths from smallpox, or a mean annual death rate of 213 per million. It is no wonder that the German medical officers are wont to point out with pride the distinction between the conditions of the French and the German cities in this respect, and the reports of the Comité Consultatif d'Hygiène of France occasionally contain mournful admissons of the same fact.

In Denmark the records pertain only to the towns, 74 in number, with a mean population of about 725,000. The deaths from smallpox in these cities in the twenty years, 1880—1899, show a very low annual death rate from this cause of only 4.3 per million.

Blood in Its Relation to Surgical Diagnosis.—A E. Woehnert says that, other things being equal, the patient whose hæmoglobin is near the normal point has a better chance to withstand the shock of a severe operation than one whose iron is markedly deficient. The Justus test is of value in suspected syphilis, and depends upon the diminution of the hæmoglobin in specific cases, when mercury is administered. The study of the number and kind of leucocytes is the most interesting and important part of the blood examination to the surgeon. In all pus infection we have a leucocytosis of a polymorphous variety. In a number of appendicitis cases reported last year, in which blood analysis was made, when the leucocytes numbered 15,000 or over, pus was found. The blood of cancer, when cachexia is present, often shows a leucocytosis, even when secondary infection or ulceration has not occurred. The study of the erythrocytes, which show considerable change in size and shape, will help to differentiate. In some obscure cases when we wish to know whether we have to deal with typhoid fever, appendicitis, or some other inflammatory abdominal condition, blood analysis is invaluable. The Widal reaction is diagnostic of typhoid fever, polymorphous leucocytosis of appendicitis or other inflammatory process. The presence of an eosinophilic leucocytosis may be diagnostic of trichinosis.—*Buffalo Medical Journal.*

Three Cases of Achondroplasia.—A. Jeffreys Wood and Herbert M. Hewlett report three cases of disease, and illustrate their article with pictures of the patients. In these dwarfs the arms and legs are shorter than normal, and the tissues seem redundant, often lying in folds over the shortened bones. There is a sulcus at the root of the short, thick nose; in the hand, the fingers do not lie parallel, as in a normal hand, but show a curious divergence, two fingers sloping to the ulnar side, and two to the radial tide of the midline of the hand. Mentally these children are very bright, and get on well at school. That achondroplasia existed in ancient times is shown by pictures of the Egyptian god Ptah. In the animal kingdom it is seen in dachshunds and bassets. It is a fetal bone disease. No beneficial treatment is known.—*Intercolonial Medical Journal of Australasia.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE CARE OF THE INSANE IN NEW YORK STATE.

THROUGH the untiring energy of a band of devoted workers in France, England, and America, the insane of those countries now receive the care and intelligent treatment which their condition demands. Before these philanthropists took up the cause of the mentally afflicted, the manner in which institutions for lunatics were conducted was a disgrace to civilization. These facts are, however, too well known to need repetition.

Dr. Robert M. Elliott, Medical Superintendent, Long Island State Hospital, Flatbush, Brooklyn, N. Y., read before the Brooklyn Society for Neurology, on March 27 of this year, a paper on the insane of New York State, in which he sketches the conditions that existed at the time of the passage of the State care law in 1889, and gives a brief description of the results which have followed, and subsequent laws which have been enacted.

In 1889 there were six State hospitals. They were Utica, Willard, Hudson River, Buffalo, Binghampton, and Middletown, and contained, in the aggregate, 5,202 patients. The three county asylums exempted from the operation of the State Care Act, New York, Kings, and Monroe, contained 6,970 patients, and there were some 2,240 cared for in almshouses in the various counties throughout the State.

The treatment of the patients in many of the almshouses, and in other buildings set apart for them by the county authorities, is given in the first annual report of the State Commission in Lunacy, and was so notoriously bad that, in the course of two or three years, accommodations were provided for all of these unfortunates in the several State institutions. The asylums of the three exempted counties, although possessing many defects, were in all respects far superior to the almshouses. In 1891 the Monroe County Asylum was transferred to the State; Kings followed in 1895, and New York in 1896. The State hospitals now number fourteen, and the total number of inmates is, in round numbers, 23,000.

Speaking of the nurses, Dr. Elliott says: "Our nurses are trained especially in the care of those afflicted with mental diseases. It is a specialty in the field of nursing, and a knowledge of nursing in general, of anatomy, physiology, hygiene, dietetics, materia medica, medical and surgical nursing, etc., are just as important in this specialty as is a knowledge of general medicine and surgery to the neurologist or ophthalmologist; the principle involved is the same. General hospitals, at the present time, afford practically no opportunity for experience or instruction in this line of work."

The ratio of medical officers to patients in the State hospitals is about one to two hundred, according to the writer, exceeding that of most European countries and some of the other States in America. The greatest difficulty with which the State hospitals of New York have to contend is overcrowding.

In addition to the resident medical service, there is connected with most of these hospitals a consulting staff composed of specialists of the highest standing.

The dietary has received careful consideration. Prof. W. O. Atwater of Wesleyan University was called in by the Lunacy Commission to investigate the matter of food consumption in the State hospitals, with the result that, after conducting a series of investigations at several of the institutions, he recommended a diet table which he was of the opinion would meet the requirements of the majority of the patients, but which is varied when considered necessary. Discussing the recovery rate under the improved management of the insane, Dr. Elliott acknowledges that there has been but little advance in this respect, and then proceeds to touch upon, perhaps, the most important point in the treatment of the insane. He says that persons are scarcely ever committed to a State hospital until they are dangerous to their relatives and neighbors. The evolutionary period is too often overlooked, and treatment is not sought until the symptoms culminate in pronounced mental disorder. The question of psychopathic hospitals is one which is at present receiving a great deal of attention on the part of medical men interested in mental disease. A movement is on foot to have separate hospitals for this purpose in the Boroughs of Manhattan and Brooklyn for a limited number of cases. These institutions will be in the nature of probationary homes for those who are in the incipient stage of insanity, where they will be treated and will not be adjudged insane until all steps have been taken to discover whether there is any chance of recovery for them.

The MEDICAL RECORD has advocated the establishment of such hospitals, either as departments of a general hospital, or as separate institutions. A reception department for the insane will shortly be opened at the Albany General Hospital, and the erection of others, for a like purpose, is contemplated elsewhere.

Dr. Elliott concludes an interesting paper by referring to the connection between alcohol and insanity. He is a strong adherent to the belief that alcohol is one of the most potent causes of mental affections. It is satisfactory to learn upon good authority that the State hospitals of New York are well managed, and that the treatment of patients therein will compare favorably with that of those similarly afflicted, and in a like situation, in other countries.

The Cholera in Egypt is believed to be gradually subsiding. For the week ending October 18 there was a daily average of 114 new cases and 87 deaths reported to the health authorities. Cairo is said to be practically free from the disease.

LORENZ'S OPERATION FOR CONGENITAL DISLOCATION OF HIP.

For some days the public press has given considerable space to the bloodless operation for the reduction of congenital dislocation of the hip first described by Professor Lorenz of Vienna. It has been occasioned by Professor Lorenz's first appearance here.

The operation is not new to surgeons in this country, having been performed successfully many times during the past five years. The attention of the profession was first called to it when Lorenz presented to the Twenty-fifth Congress of the German Association of Surgeons at Berlin, May, 1896, four patients upon whom he had operated by what he termed an entirely new method. After considerable discussion by the Congress, of whom Bergmann was president, it was generally agreed that a new principle in treatment had been discovered.

Following rapidly upon this appeared full details of the technique of the operation through Lorenz and his special pupils. The first complete description of the operation appeared in the Medical Record May 29, 1897, in an article by Dr. George R. Elliott, a pupil of Professor Lorenz, entitled "Congenital Dislocation of the Hip-Joint, with Special Reference to the New Non-cutting Operation of Lorenz, for Reposition of Same—Presentation of Patient Under Treatment." This article appeared before Lorenz himself had written fully upon the technique of his operation, and was copied widely. Lorenz says in his recent work on the subject (1900) that Elliott had, according to his knowledge, performed the operation for the first time in America, as reported by the Medical Record, and that the steps of the operation had been followed out with a complete knowledge of the subject. After quoting at length from the Medical Record regarding the test for stability of the joint after reduction, he says, "In this description alone lies the surest proof that Elliott accomplished a real reposition."

Referring to the Medical Record, it will be found that the first step in the operation consists in the reduction or bringing the head of the dislocated thigh to the level of the acetabulum. The patient is anæsthetized to a degree of extreme muscular relaxation. A band is passed around the perineum and another about the ankle, the latter attached to a screw-extension apparatus. The extension is evenly exerted, while the operator grasps the muscles of the thigh, manipulating them while extension is going on. When the head of the femur is brought below the Nélaton line extension is suspended, and is followed by the second step in the operation—the wedging of the reduced head of the thigh bone into the acetabulum. This is styled reposition.

The chief anatomical barrier is the anterior fibrous wall of the capsule hugging closely the surface of the acetabulum. Although the head is in the proper position to enter the acetabulum, no amount of force will drive it in. The operator, standing on a stool, seizes the thigh, flexed at right angles to the trunk, with one hand, and with the other grasping the head of the femur, he, by a system of extension, combined with rotation and gradually increasing abduction, opens the way into the dormant-lying acetabular pocket. If the reposition is successful, the head of the femur is felt to leap over the posterior edge of the acetabulum, and the surgeon feels at once that reposition has taken place.

The third and final step in the operation has for its object the formation of a solid acetabulum. By manipulation the soft parts of the acetabular cavity may be molded, but the substantial changes occur when the patient is allowed to go about. In order to retain the head of the bone in contact with the acetabulum, and thus reawaken the process of growth so long dormant, the thigh is flexed at about 90° of abduction. The fixation is made with a plaster-of-paris bandage carefully applied about the pelvis, and extending to the knee-joint of the affected side. After a few days the child is urged to walk. Every step tends to drive the head of the bone deeper and deeper into the acetabulum. Growth is reawakened, the parts are reactivated, and a nearthrosis is gradually built up. Lorenz styles this treatment—the lodging of the head of the bone with the body weight, together with the reposition, as the two chief points in the operation—as decidedly original with him."

Formerly Lorenz removed the first fixation period at the end of three months, and usually subjected the patient to a second fixation period of three months. He now advocates rather longer fixation periods..

In 1888 Paci of Italy presented a treatment that aimed at restoration of the congenitally dislocated hip-joint. Paci divides his operation into four stages, which he calls tempi:

1. Flexion of the leg and thigh upon the pelvis quite to the physiological limit. This, combined with pressure on the knee-joint, is said to bring the head of the femur out of the ext. iliac fossa to a point under the acetabulum.
2. Moderate abduction—the leg is abducted to the extent of fifteen centimeters from the lateral line of the body.
3. Outward rotation.
4. Slow extension in bed, continued three months.

To use Paci's own words, he says, "The result is often excellent, because the head has occupied its natural position in the acetabulum in such a manner that we appear to have before us a true reposition. But often the head contents itself by taking position quite in the neighborhood of the rudimentary acetabulum or beneath the anterior iliac spine." This is as strong as he expresses himself in his reply to Lorenz, published in the *Wiener klinische Wochenschrift*, June, 1896. The end product of Paci's operation is a nearthrosis formed in the vicinity of the rudimentary acetabulum and not a true reposition.

The extreme degree of abduction, 90°, is a ***sine qua non*** of a true reduction, according to Lorenz, and it is a true reposition that he insists upon. No attempt is made to establish a nearthrosis in the neighborhood. Not infrequently the end product is a nearthrosis in the neighborhood known as transposition or anterior dislocation.

The operation is especially adapted to children under five years of age. After that age a reposition is frequently impossible.

The success of the operation depends largely upon the anatomical condition of the head of the femur. A large number of so-called congenital dislocations of the hip occur at time of child-birth. Here the parts continue to develop, and there exists only a slight atrophy incident to disuse. For this class the operation is especially promising. A reposition is rapidly followed by a reactivation of the parts involved.

In another class styled true congenital dislocation of the hip, in which there are real deficiencies, such as entire absence of the head of the femur, entire absence of anything like an acetabulum, it will be readily seen that cures cannot be looked for. Surgeons familiar with the operation agree that prognosis depends upon the anatomico-embryological findings present; in many cases the deficiencies being so marked that reactivation after reposition is impossible.

Lorenz claims something like 60 per cent. of successes in his operations so far performed. Other operators place the percentage of cures at 40 per cent.

Surgeons, accustomed to reduce dislocations along well-defined anatomical lines, see in this operation nothing remarkable, but rather the following of a technique based upon an intelligent understanding of rudimentary anatomical findings, which, in well-selected cases, leads to a large percentage of cures of a distressing deformity. They agree in rendering full credit to Lorenz for having discovered and developed that technique.

A STUDY OF THE LATE EMILE ZOLA.

The recent tragic death of Emile Zola has drawn the attention of the world to that extraordinary man, and the question of his mental and moral characteristics, and of his nervous and physical make-up has again arisen. Anthropologists have always taken a peculiar interest in Zola, viewed from the standpoint of degeneracy, not only because he appeared to offer an excellent example of the truth of the theory that there is some connection between genius and degeneracy, but also because he allowed, a few years ago, a study of himself to be made by several French specialists. Dr. Arthur Macdonald at the time wrote a paper on the subject, giving the conclusions come to as a result of these investigations, which was made the text for an article in the Medical Record of September 17, 1898.

Since then Dr. Macdonald has written other papers dealing with Zola's personality, which, in the light of recent happenings, are worthy of consideration.

It is thought probable that Zola inherited from his parents and grandparents a vigorous physique, and from his mother a nervous gout, or neuroarthritic condition. The hardships which he underwent when a young man served to give form to his congenital neurotic state. His nervous troubles increased more and more; and up to the age of forty he suffered continually from ill-health. At about the age of thirty-five morbid ideas made their appearance; although such ideas do not seem to have had any antecedents in his youth. When, however, he began to be successful, most of the nervous symptoms took flight, and his health became in every way better.

Zola was a little below the average in standing and sitting height, but in arm reach he was about the average. His head was larger than that of the ordinary man. The antitragus of the ears was almost absent, and the border adhered to the cheek. The upper left eyelid was somewhat low. The wrinkles on the forehead existed as early as the age of six. By some, wrinkles in children are thought to be an indication of dulness, while Manouvrier regards them as a sign of emotivity. In Zola's case, his nearsightedness may have accounted for the wrinkles in his childhood.

When in a state of repose and looking at a distance, the left eyebrow was notably lowered; this was probably due to an orbicular contraction of long standing, and might be considered as a neuropathic stigma.

With regard to Zola's nervous system, there existed in him a certain lack of nervous equilibrium, an exaggerated morbid emotivity, which, under the influence of slight excitations, caused disordered and painful reactions.

This condition, remarks Dr. McDonald, frequently accompanies intellectual superiority, develops with exercise of brain and mind, and tends gradually to increase the lack of nervous equilibrium.

His visual perceptions were feeble, owing to nearsightedness, and in perceptions of hearing he showed a very poor musical ear.

In speaking he had no qualities of an oratorical nature, he was very nervous and timid, and emotion inhibited or paralyzed him.

Zola possessed an excellent memory when young, but as he grew older his memory became less reliable, and his concentration of attention was short.

While physically he was somewhat abnormal in his sensations, yet not so in all his manifestations of sensibility. Fear was the principal emotion in him connected with the instinct of self-preservation. He had no fear of dying suddenly, and never had any ideas of suicide. Zola had a multitude of morbid fancies, but they affected his mental equilibrium but little. His will power was great, and his chief characteristic is said to have been tenacity, and he was always master of his actions.

The conclusions arrived at by the French scientists, with which views Dr. Macdonald is in agreement, were that Zola was a neuropath, but neither epileptic nor hysterical, nor was there the least sign of mental alienation. The term "degeneracy" did not wholly apply to him. Magnan classed him among those degenerates who, though possessing brilliant faculties, have more or less mental defects, while Toulouse said he had never seen an obsessed or impulsive person who was so well balanced. Nevertheless, the final judgment was that Zola was a neuropath—that is, a man whose nervous system was painful.

Whether an abnormal nervous system is a *sine qua non* of genius or exceptional talent is a question that has not yet been definitely answered, and probably never will be answered. But it would seem that it must be something more than a coincidence that so many of the world's greatest men have had undoubted stigmata of degeneration. The physically perfect man—or as nearly so as may be found—is seldom or ever a genius, and does not often possess great talent. On the other hand, the diseased men of genius can be cited almost without number. This one fact would appear certain, that most great men, and especially the imaginative of this class, are of nervous temperament and often inclined to be neuropathic.

A French Physician's Views on the Increase of Cancer.

It has come now to be an article of faith that cancer has increased and is still increasing at a very rapid rate. Statistics have been forthcoming from every country—where such things are kept—in support of these views. Doubtless the disease is far more prevalent than formerly, but, nevertheless, it is somewhat encouraging and refreshing, after hearing for so long pessimistic opinions as to the spread of cancer, to be told by a well-known authority that the reports as to its alarming increase have been much exaggerated, and that the fears engendered thereby are not altogether justified by the facts of the case.

Prof. R. de Bovis of the Reims School of Medicine has recently written an article on what he thinks are fallacies in cancer statistics, a part of which is transcribed and commented on in the *British Medical Journal* of October 4. He points out a matter which is insufficiently recognized, that statistics confined to the incidence of cancer in hospitals and in post-mortem rooms can convey no idea of the frequency of cancer in a given town or country. The statistics of death occurring in civil life are alone generally available for the purpose. In view, furthermore, of the imperfections of registration and certification of deaths at an earlier period, Professor de Bovis is quite right in insisting that our statistical researches must be confined chiefly to the last twenty years.

Professor de Bovis' article is far too long to more than touch upon certain portions of it. His remarks concerning the relative frequency of cancer in the two sexes are especially interesting.

First of all, Professor de Bovis shows how the mere comparison of the crude death rate from cancer in each of the two sexes is fallacious, and that corrections must be made in view of the fact that 100,000 females would comprise a larger number of aged than the corresponding number of males. In Prussia, in 1898, there were 100 deaths of men from cancer to 113 among women; but if the comparison be confined to the population over twenty-five years of age, the relative numbers were 100 to 109. Even this correction does not suffice, as shown by the paper of Messrs. King and Newsholme. Comparable statistics were obtained by calculating the death rate on a "standard" population, and by giving separately the death rates for different age-periods. It offers the disadvantage that it cannot give the *idée d'ensemble* of the relative frequency of cancer in male and female which is given by the former method.

According to M. Laspeyres, between the ages of thirty and fifty years the female is greater than the male mortality from cancer, the contrary being true from fifty to seventy. Recent statistics show an apparent increase of cancer in the male much greater than in the female sex. Thus in 1877, in England, for every 100,000 inhabitants of all ages, the male deaths from cancer to the female were as 100 to 193; in 1897 they were as 100 to 146. This decreasing ratio of female cancer is unhesitatingly ascribed by Professor de Bovis to the fact that male cancer is more commonly inaccessible than female cancer, the increase in males being probably more apparent than real.

M. de Bovis arrives at the following general conclusions from his close investigation of this subject: Careful study of statistics contradicts more than it confirms the supposed alarming increase of cancerous affections signalized by most writers; this increase is, perhaps, real, but the alarms expressed are without doubt absolutely out of proportion to it.

Alcohol-Contaminated Air.

Our esteemed contemporary, the London *Lancet*, in its issue of October 4, treats of this subject and incidentally adds yet another terror to those who frequent places in which alcoholic drinks are stored or retailed. Nevertheless, it is an excellent procedure to point out all the dangers to which the wine-bibber is subjected, as it tends to further the cause of temperance.

The *Lancet* annotation in question says: "There can be little doubt that the air of distilleries, wine and spirit vaults, and drinking saloons must, at times, contain appreciable amounts of alcohol, and the question has arisen as to whether air containing traces of alcohol would be prejudicial to health."

The fact is then referred to that where wine and spirits are stored there is invariably an alcoholic smell, and that a walk through the cellars at the London Docks has much the same effect as imbibing too much alcoholic liquor. In the same way the great sherry bodegas in the south of Spain produce, on a person not used to them, the sensation of being under the influence of strong drink, while the great stores at Cognac affect some individuals with a feeling of sickness. The more volatile constituents of wines and spirits evaporate into the air most quickly, and the volatile ethers would thus prevail. After referring to the ethereal qualities of sherry, the article proceeds thus: "There would, therefore, appear to be some ground for concluding that when the air is impregnated with the volatile vapors of spirits or wines it has a marked influence upon the health. Whether this effect would be pronounced or not upon those inhaling the air day by day does not appear to have been ascertained with certainty. It is probable, however, that at any rate some slight deterioration of health would take place. . . . According to an examination made of the air of a distillery, it would appear that no less than an ounce of proof spirit, or half an ounce of absolute alcohol, may be present in five cubic feet of air, and since the alcohol, by the medium of the lungs, would rapidly gain access to the circulation, the conclusion must be in favor of the view that such air would, in the long run, be detrimental to health, and that in such case special arrangements for particularly efficient ventilation are indicated."

It stands to reason that few saloons can be healthy places in which to pass much time. The fumes of the spirits probably have a harmful effect on health, and, allied with the other conditions which usually prevail in these resorts, defective ventilation, a smoke-laden atmosphere, and often overcrowding, must exercise a deleterious influence on those who are constant visitors to saloons, and especially on the bartenders who are compelled to spend a large part of their lives in them.

It is a matter for congratulation that in America there are no women behind the bars in saloons.

The Care and Custody of the Criminal Insane.

How best to treat the criminal insane is a problem the solution of which has not been, as yet, by any means reached. It was gravely proposed in a book, written some few years ago, that it would save much expense and, in the long run, would be the most merciful plan, if such people were put to a quiet and painless death.

The methods of dealing with this class, however, which are pursued in New York, Illinois, Massachusetts, and Michigan meet the exigencies of the situation fairly well. In these States criminal State hospitals have been established, to which are sent those criminals who have been adjudged not responsible for their actions, and who are kept there during the term of their sentences, unless they recover. In which case they are returned to the penal institution whence they came, with a certificate of their recovery, to finish their terms there. Should they not recover during their terms, they remain in the hospital, not only until the term expires, but afterward, until death comes or it is considered reasonably safe to release them.

The weak link in this system, according to Dr. H. E. Allison, is in the fact that in New York some of the penal institutions are not sufficiently careful to transfer their insane to the hospitals provided for the purpose. The efficiency of the various institutions, he declares, may be judged by the way the insane are sent to Matteawan. If from a prison with a population of a thousand inmates, this hospital receives thirty or forty insane every year, and from another institution, with a similar population, no inmates are received, then it must be inferred that in the latter institution there is not enough attention paid to the individual, and that it is not doing the reformatory work that it ought to accomplish.

Dr. Allison further says that the number of life convicts who are insane is about 25 per cent. of the total number of life men in New York, and there is about the same proportion in Massachusetts and Broadmoor, England, showing that a great many life men either become insane while undergoing imprisonment, or have committed their crimes through insanity, which was not recognized at the time of their trial and conviction. There is a great prejudice against the plea of insanity as a defence for crime, and many insane men are sent to prison. Numerous lunatics are dangerous who do not succeed in committing murder, for an insane man's aim may be defective, and such persons may be sentenced for from three to five years who have active and menacing delusions. At the end of that time they are set at liberty to be again threatening society. Dr. Allison thinks that such men ought to be locked up until reasonably safe for them to be at large.

The system in force in New York and some other States with regard to the custody of the criminal insane is a good one. It seems but proper that such persons should be detained in an institution established for the purpose, and not in the ordinary prisons.

The method followed in New York State in the care of the criminal insane is characterized by humanity and intelligence, and if defective in some respects, it is at any rate decidedly in advance of some of the methods pursued elsewhere.

Health in Schools.

There is nowadays a wise appreciation of the need of caring for the physical well-being of children at school. It is thoroughly recognized that the young must be properly looked after in every way, in order that the nation may be composed of vigorous and sound individuals. New York has been among the pioneer cities in endeavoring to bring up her rising generation so that they shall possess the sound mind in the sound body.

At the Section of Educational Science, at the recent meeting of the British Medical Association, Professor Sherrington, F. R. S., submitted the report of the committee appointed to inquire into "the conditions of health essential to the carrying on of the work of instruction in school." The health conditions considered were: (1) Bodily nourishment; (2) clothing; (3) housing of children in schools; (4) the working of the bodily functions and organs of sense; (5) physical exercise; (6) the apportionment of time to work and rest, including length of lessons and holidays; (7) healthy tone of mind and morals; (8) preventive and precautionary measures against infectious diseases.

Anthropometrical and physiological tables had been also compiled and tabulated. The knowledge of hygiene possessed by school teachers was likewise investigated. The committee concluded that school authorities very imperfectly realized how important hygiene was for school life; they were content to allow teachers to remain in ignorance of this knowledge, or to accept as evidence of sufficient experience certificates which guaranteed merely a superficial and second-hand knowledge. Finally, the committee urged the British Medical Association to memorialize the Education Department to adopt some more thorough and practical test of a teacher's experience of hygiene; and secondly, further to protect health in school life by making practical knowledge of hygiene as applied to school life an essential qualification for those to whom it entrusted school inspection."

The large cities of America, as New York and Chicago, are, in many respects, in advance of British cities with respect to their care of school children, but as yet these scarcely reach the standard recommended in the report of the English committee. The adoption—at least as far as was possible—of the committee's suggestions could not but be to the benefit of school children physically and mentally. The only fear is that there perhaps may be, nowadays, somewhat too great a tendency to maternalism, as coddling the young is nearly as harmful as neglecting them.

Extraction of Iron from the Vitreous Chamber by Means of the Giant Magnet—A New Procedure.

Dr. Charles J. Kipp of Newark, N. J., records, in a recent number of the *Archives of Ophthalmology*, two noteworthy cases of removing metal from the vitreous chamber by magnetic attraction. The cases mentioned by him—and especially the first case—are decidedly uncommon. In the one he removed a large piece of iron through the wound of entrance, after it had become entangled and could not be budged, by the successful application of the familiar law of magnetic polarity.

The second case calls for notice because of the complete clearing up of the opacity of the lens following the passage through it by the foreign body.

The first case is described as follows:

A man was struck in the left eye by a piece of metal, and was seen by Dr. Kipp a few hours after the accident. There was no irritation, and the conjunctiva was not infected. The cornea was clear, and in the sclera, close to the outer margin of the cornea in the horizontal meridian, was a linear wound about 2 mm. in length, parallel with the margin of the cornea, from which vitreous body was escaping. The anterior chamber was very shallow, and contained a little blood; the pupil was somewhat dilated. The iris near the wound was torn, the lens clear as far as it could be seen, and the vitreous full of dark, floating opacities. With the ophthalmoscope a dark mass could be seen at the bottom of the vitreous chamber. The eye was then placed close to Hirschberg's simplified sideroscope, and the needle indicated at once the presence of iron in the eye.

When the eye was brought up to the giant magnet, and while still more than two inches from it, as soon as the current was turned on a large, glistening piece of metal, back of the lens, was seen to rise up and rush toward the outer part of the eye, where it caused a marked bulging of the sclera, at a point about 6 mm. posterior to the wound of entrance. One end of the piece of iron became fastened, so that to get it out of the eye nothing short of a large incision in the sclerotic seemed practicable. It, however, suddenly occurred to Dr. Kipp that the end of the iron might be dislodged by bringing the like pole of the magnet to act upon it. Accordingly, the magnet was turned around on its pivot, and as soon as the other pole came near the eye, the iron was seen to swing around in the vitreous chamber, the bulged part of the sclera became flat, while the other end of the iron came toward the wound of entrance and rapidly shot out on to the magnet. The wound soon closed, and there was no reaction, but the lens, in the course of a few weeks, became opaque throughout. The eye now has good perception, and the visual field is intact. The iron removed measured 18 mm. in length, was about 2 mm. in width atone end, and about 1 mm. at the other, where it was pointed and was quite thin. It weighed 10 mg.

News of the Week

Major William C. Gorgas, recently relieved from duty as chief health officer in Havana, has been appointed by the Surgeon-General delegate to represent the United States Army at the Egyptian Medical Congress to be held at Cairo, December 16—23, 1902.

Yellow Fever Experiments Forbidden.—Secretary Tamayo of the Cuban Cabinet has recently issued an order forbidding the experimental inoculation with yellow-fever virus of non-immunes by means of the bites of infected mosquitos. Insects which have bitten a person with yellow fever are in this order officially declared to become infective at the expiration of ten days.

The Italian Medical Congress.—The twelfth annual meeting of the Italian Congress for Internal Medicine will be held in Rome, under the presidency of Dr. Baccelli, on October 28—31.

New Head of the Bureau of Ethnology.—Prof. William H. Holmes has been placed at the head of the Bureau of Ethnology in Washington to fill the vacancy caused by the death of Major John W. Powell.

Alvarenga Prize of the College of Physicians of Philadelphia.—It is announced that the next award of the Alvarenga Prize, amounting to about $180, will be made on July 14, 1903, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college, Dr. Thomas R. Neilson, M.D., on or before May 1, 1903. Each essay must be sent without signature, but must be plainly marked with a motto, and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it, shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga prize for 1902 was not awarded, the committee having decided that no essay of sufficiently high standard was submitted in competition.

Street Bacteria.—Dr. John McG. Woodbury, Commissioner of Street Cleaning, lately began a series of investigations with the assistance of James Ewing and others to determine the nature and number of microorganims in the air of our city streets, and show the influence of clean gutters and street pavements upon the healthfulness of neighborhoods. Gelatin plates were exposed for determined periods in various parts of the city and at different levels above the street, and after a period of incubation the number of colonies on each was counted. This number varied from five in clean residential streets, in which there is but little wagon traffic, to several hundred in the crowded tenement districts on the East Side.

The Cost of Hospital Treatment.—At a recent meeting of the Board of Estimate of this city, the following comparative statement of the average daily cost per capita for ward patients in the larger hospitals in this and other cities was presented: Presbyterian Hospital, $2.34; St. Luke's Hospital, $1.82; Mount Sinai, $1.50 to $1.55; St. Vincent's Hospital, $1.08; St. John's Hospital (Long Island City), $1.10; Roosevelt Hospital, $2.01; Massachusetts General (year 1900), $2.15; Rochester City Hospital, $1.61; Lakeside Hospital (Cleveland, O.), $2.14; Boston State Hospital, $1.92.

Big Medical Fees.—It would be interesting to know, says the *Hospital Gazette*, what it cost the King in medical and nursing fees during his late serious illness; but curiosity is not likely to be gratified on this point for some time to come. For his four weeks'attendance at Sandringham prior to the recovery of the King from typhoid fever, in 1871, Sir William Gull received £10,000. Twice this amount, says the *Vegetarian*, was paid to Sir Morell Mackenzie for his treatment of the late Emperor Frederick. The doctors who attended Queen Victoria in her last illness received 2,000 guineas each; while Dr. Lapponi's skill in removing a cyst from the Pope's side a few years ago was recompensed with $2,500. Dr. Dimsdale, for his journey to St. Petersburg and vaccination of the Empress Catherine II., received £10,000 as his fee, £5,000 for travelling expenses, and a life pension of £500 a year. According to the newspaper reports, Dr. Lorenz of Vienna was brought to Chicago to operate on a child with congenital dislocation of the hip, at a cost of $100,000 and traveling expenses for himself and assistant.

An Illegal Practitioner.—A "palmist" was convicted in Special Sessions a few days ago of practising medicine without being registered as a physician. Sentence was suspended for a week. The man said he got his prescriptions from a legal physician, and the latter, being called to the witness stand, acknowledged that he had written prescriptions for the accused.

Increased Grant to Hospitals Asked For.—At a recent meeting of the Board of Estimate of this city, the Chief Examiner of the Accounts of Institutions presented a report in which he recommended that the rate which the city pays the private hospitals for medical and surgical cases be raised from 60 and 80 cents to 70 and 90 cents respectively.

Associated Physicians of Long Island.—A meeting of this society was held at Riverhead on October 18, with an attendance of 130. The following papers were read and discussed: "Shall Marriage Be Medically Controlled," by Dr. William B. Savage of East Islip; "Points of Similarity and Difference in the

Outset of Typhoid Fever and Appendicitis," by Dr. William F. Campbell of Brooklyn; "Relation of Obstetrics to Surgery," by Dr. Ralph H. Pomeroy of Brooklyn; "Acute Contagious Diseases of the Eye," by Dr. James H. Ingalls of Brooklyn.

Dr. William H. Bates of this city, who disappeared on August 30, after having left his home ostensibly to perform an operation, is reported to have been found by his wife in London. It is said that he was attending a post-graduate course at the Charing Cross Hospital. His story was that he left his office on August 30 with a man who he thought was a former classmate, and went to a sailing vessel in the East River, where he performed an operation on a man suffering with a mastoid abscess, and stayed all night. His next recollection was of being on a steamship approaching England, then of being in the streets of London, and of deciding to take a course at the Charing Cross Hospital. The gaps in this account he could not fill, but he seemed certain that he had not been drugged.

Reciprocity in Medical Licensure.—The Wisconsin State Board of Medical Examiners has made an announcement, says *The New York Times*, that thirty States of the Union will unite in common laws regard ing the practice of medicine, so as to make possible extensive reciprocity. Hitherto this movement has included only four States of the Middle West, but it is now stated that bills will be introduced into the legislatures of all the Eastern States for the purpose of equalizing the requirements for medical practice, and so making medical certificates interchangeable, and establishing practical reciprocity in medical licensure.

Initials for Trained Nurses.—The New York State Nurses' Association, which met in Rochester this week, took up the question of a title for trained nurses. The Legislative Committee of the association learned that before taking steps toward securing desired legislation for trained nurses it would be necessary to decide upon a title similar in significance to the M.D. of the physician. The following were some of the titles suggested: T. N. (trained nurse); G. N. (graduate nurse); R. G. N. (registered graduate nurse), and R. N. (registered nurse).

The Doctor in Politics.—A politician in New York recently established his popularity among those of his own kind, and defeated his antagonists, by the lavish distribution of shoes, beer, beef, and other things to eat and to wear. A New Jersey candidate for congressional honors has improved upon this scheme by throwing in free medical advice. One of the cities in that progressive State was recently placarded with large posters announcing that, "by the generosity of Hon. ———, free medical attendance and dispensary service are given to all who are unable to pay on Wednesday, Thursday, and Friday afternoons, from 12 noon until 2 P. M. A skilful physician attends." The poster also gives the name and address of the doctor selected by the candidate.

Rules for Burial Following Death from Infectious Disease.—The Maryland State Board of Health has published the following regulations regarding the disposal of the bodies of those who have died of any infectious disease: "In every case of death from cholera, bubonic plague, or smallpox, the body is to be taken charge of at once by the local health officer and buried or cremated within twenty-four hours. Transportation of such bodies by rail or steamer is absolutely forbidden. Such a body must be prepared for burial with as little disturbance of its immediate surroundings as possible. It shall be wrapped in the bed coverings, secured by bandages; shall be placed in a tight coffin; the wrappings shall be saturated with 40 per cent. formalin or solution of bichloride of mercury, 1 to 500, and the coffin shall be closed at once. In the discretion of the local health officer a competent undertaker may be allowed to embalm such a body, provided the body be not removed for that purpose from the spot where death occurred. The vehicle in which such a body has been transported to the place of burial shall be washed in a solution of bichloride of mercury, 1 to 1,000. In every case of death from diphtheria, membranous croup, or scarlet fever, the body shall be prepared at once for burial by arterial or cavity embalming, or by covering with a layer of absorbent cotton not less than one inch thick, securely bandaged or rolled in a sheet, this covering to be saturated with a solution of 40 per cent. formalin, or bichloride of mercury, 1 to 500, and the body to be enclosed in a tight coffin at once. The head and face need not be thus covered, provided the scalp and face and the cavities of the mouth and nose have been disinfected with an approved germicidal solution. The lead of the coffin may have a fixed glass panel over the face, to permit inspection, but not such as will permit exposure to the air. It shall be unlawful to open the coffin, except on written consent and in the presence of a local health officer. Only persons of adult age shall act as pallbearers in such cases. Interment shall be made within twenty-four hours of the time of death. Only members of the immediate household and necessary attendants shall be admitted to the house."

The Fourteenth International Medical Congress.—The following is a summary of the work mapped out for each of the sixteen sections of the Madrid Congress, to be held in April, 1903:

In the Section of Anatomy (including anthropology, comparative anatomy, embryology, descriptive anatomy, normal histology, and teratology), which will be presided over by Professor Santiago Ramon y Cajal, the following subjects are proposed for discussion: (1) What is the best method of didactic exposition of the nervous system? (2) The positive value of anatomical measurements for the racial identification of individuals; (3) The structure of nerve cells; (4) The origin of fibroblasts in connective new formations, normal and pathological.

In the Section of Physiology (President, Dr. Gabriel de la Puerta y Rodenas), among the subjects set down for discussion are the physiological action of saccharin, and the influence of glandular poisons on muscular contraction.

In the Section of General Pathology (President, Dr. Amalio Gimeno y Cabanas), Dr. Marchiafava of Rome will introduce a discussion on parasitism in neoplasms; there will also be discussions on the genesis of sarcomata; blastomycetic lesions; the desirability of a revision of the classification and description of known bacteria; and vaccinations with cultural and chemical liquids.

The Section of Therapeutics (President, Dr. Benito Hernando y Espinosa) will discuss the relations between the chemical composition of medicaments and their physiological action; the dangers of the so-called intensive medication in chronic diseases and chiefly in tuberculosis; the utility and dangers of intraspinal injections of cocaine in medicine and in surgery; the mechanism of the physiological and therapeutic action of hypnotics and narcotics; intravenous therapy; the treatment of tetanus by Baccelli's method; the therapeutic valuation of antitoxin serums; hypodermic injections, their pharmaceutical significance and the desirability of preparing a pharmacopœia unifying the procedures for making and preserving these preparations.

In the Section of Pathology (President, Dr. José Calvo y Martin) there will be discussions on the etiology and prophylaxis of malaria; the application to clinical medicine of the new researches on the physical and chemical properties of blood serum and diet in typhoid fever.

The Section of Nervous Diseases (President, Dr. José Maria Esquerdo y Zaragoza) will give special attention to toxic and infectious insanities; the delimitation of the pathological nature of crime, and the intervention of psychological medicine in the reforming treatment of criminals.

The Section of Children's Diseases (President, Dr. Francisco Criado y Aguilar) will discuss the therapeutic value of serumtherapy in diphtheria; the treatment of club-foot; the treatment of tuberculous disease of joints; infant feeding; acute non-tuberculous meningitis; infantile rheumatism and its relation with heart disease and chorea; alcholism in children.

In the Section of Dermatology and Syphilis (President, Dr. Manuel Sanz e Gombin) the following subjects will be discussed: Blenorrhagia from the medico-social standpoint; para-syphilitic diseases; retrospective diagnosis of syphilis; treatment of pruritus.

In the Section of General Surgery the subjects proposed for discussion are deaths following operation and indications for surgical intervention in diseases of the stomach. In the Subsection of Neurology there will be discussions on the remote results of surgical intervention in malignant tumors of the kidney, and on the comparative value of the means at our disposal for the appreciation of the functional condition of the kidney.

In the Section of Ophthalmology (President, Dr. Santiago de los Albitos) there will be discussions on the surgical treatment of affection of the lachrymal passages; the necessity of unification of optometric scales; optic neuritis in the course of acute affections; and the action of medicaments on the pupil accommodation and intraocular tension.

The Section of Oto-Rhino-Laryngology will discuss the causes of deaf-mutism; cholesteatoma; the after-treatment of operative procedures on the ear; is surgical intervention in every kind of laryngeal cancer and in all its phases desirable from the medico-social point of view, and the local treatment of laryngeal tuberculosis.

In the Section of Obstetrics and Gynecology (President, Dr. Eugenio Gutierrez Gonzalez) there will be discussions on the indications for hysterectomy in acute puerperal infections; the treatment of placenta prævia; pathogeny and treatment of chronic cellular and peritoneal inflammations of the pelvis; indications and results of opotherapy in gynecology; the conservative surgery of lesions of the adnexa; the early diagnosis of ectopic pregnancy; the treatment of urethrovaginal fistulæ; induced abortion and premature confinement in its relations with natural law, theology, medicine, and the penal law.

The Section of Military Naval Medicine and Hygiene (President, Dr. Antonio Serrano y Borrego) will discuss the tuberculosis problem in armies; the advantages and disadvantages of compressed medicaments in campaigns; military life and affections of the nervous system, particularly insanity; the prophylaxis of syphilitic and venereal diseases in armies; the hygienic problems of feeding in besieged places.

In the Section of Hygiene and Epidemiology (President, Dr. Felix Guzman y Andres) there will be discussions on the prophylactic value of disinfection and the methods generally followed; the means of preventing the spread of dysentery; the desirability of establishing sanitary custom-houses on the land frontiers of countries; the utility of antituberculous dispensaries as a means of increasing vital resistance in the poorer classes.

The Section of Forensic Medicine and Toxicology (President, Dr. Adriano Alonzo Martinez) will discuss the capacity and responsibility of degenerates and the localization of poisons.—*The British Medical Journal.*

The Late Dr. Abel Mix Phelps.—At a meeting of the Faculty of the New York Post-Graduate Medical School and Hospital, held on October 8, 1902, the following minute was adopted: In the death of Professor A. M. Phelps our school has lost a teacher, and the medical profession is deprived of a member whose energy cleared the way for great progress in his field of work during the past twenty years. His was the spirit of the pioneer. Not content with things that have been done, but ever restless to find new vistas with new horizons, his single-hearted devotion to the development of what is best in orthopedic surgery led him to engage in a constant warfare of ideas. No matter whether the ideas were those of his colleagues or his own, no matter whether he was right or wrong, his energy gave life to the subject and set men to thinking. It is such active lives as his that keep subjects alive, that keep men aroused, and lead them to their utmost, and when this is for no selfish end, but solely bent in the interest of science, we have a public benefactor whose usefulness exceeds that of the capitalist, who gives his million of dollars to the most worthy charity. The capitalist gains his fortune through his guidance of the work of others, and the scientist adds to the total of the world's knowledge by stimulating others to follow in his lead of investigation, or to take long steps in progress at his suggestion. In the professions there is a tendency for men to fall asleep upon the soft pillows of concensus of opinion, but men like Dr. Phelps realize that concensus of opinion is often wrong, because it represents the lines of least resistance, and he turns all sleepers out and made them uncomfortable until they had made their own new opinions. Dr. Phelps was impatient with those who were contented in their work, and as impatient with himself, for he realized that great fields for giving help to suffering fellow-men lay still undiscovered.

According to human experience, greatness implies the possession of constructive motives, nobility of purpose, catholicity of view, erudition. Dr. Phelps' motives were alway constructive, his ideals were of the noble sort that included no interest before the interest of the sufferer. His views were so comprehensive that he could not long remain a partisan in any field aside from that of definite knowledge. His learning was that of the man of alert conception and of trained memory. Dr. Phelps, then, was a great man, and his opponents are the ones who would say it, sooner than he himself would have acknowledged it.

It was not in our school alone, nor in the city, nor in the State, nor in America, that his talents were recognized, but wherever in the world men are engaged in studying the things that he studied, he gave direction to their methods and force to their efforts. An influence like that of Dr. Phelps is that of the wireless telegraph, sending through invisible ether an impulse that is felt and that meets sympathetic response in minds that vibrate in unison at all distances, an expenditure of energy that finds its kinetic in the development of new knowledge. Yet he was not the one to say that he was right, only that he wanted to be right, and that he wanted others to be right.

He was proud in his strength, yet modest in the presence of those who were stronger than he. Few knew this side of his character, but those of us who knew him best knew how much of humility there was beneath his forceful bearing.

And if we speak of Dr. Phelps as the surgeon, what shall we say of him as the citizen, as the friend, as the husband and father? Matters of public interest were matters with which he made himself conversant, and whether at home or abroad he formulated views of public affairs with a clearness of view that engaged the attention of statesmen. As a friend he was loyal almost to the point of weakness. His enjoyment of life, and of his friends was that of a man whose spirit of cameraderie overlooked all failings. Beneath the stern exterior developed by men of his strength to resist external impressions there was a heart so kind and sympathetic that a tale of woe or a pathetic sight moved him as it would have moved a woman, and his kindly deeds in response to the impulse of a great and generous nature were unknown to the world at large, because he considered it beneath the dignity of a man to show any side excepting the one that accomplishes things by force.

Dr. Phelps has been taken from the home, from the profession, and from the world before his activities had reached the zenith, but the influence of such a life as his will last beyond the lives of those who felt his influence, and we, his colleagues, sorrowing in his loss, exult in the privilege that we had in knowing him.—Robert T. Morris, Reynold Webb Wilcox, Henry Ling Taylor, Committee.

Obituary Notes.—Dr. William R. Whitehead of Denver died on October 13 at the age of seventy years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1853. He saw service in the Crimean War, and was rewarded by the Czar with the Knight's Cross of the Imperial Order of St. Stanislaus. During the Civil War he served with distinction as surgeon in the Confederate Army, and, later, removed to Denver, where he occupied, at different times, the chair of medicine in the University of Denver and the University of Colorado.

Dr. EUGENEE G. CARPENTER, superintendent of the Columbus (Ohio) State Hospial, died of apoplexy on October 19, at the age of forty-four years. He was a graduate of the College of Physicians and Surgeons of Baltimore. He was assistant superintendent of the Cleveland State Hospital before his transfer four years ago to the Columbus Hospital.

A Case of Tumor of the Cerebellum.—O. T. Osborne reports the case of a woman of sixty-four years, suffering from palpitation of the heart, and vertigo occurring synchronously, without ringing of the ears, disturbance of the eyes, or nausea. An ataxic condition came on, and dizziness increased, so that the patient could scarcely turn her head without having vertigo. Epileptoid signs next appeared, and developed into epileptic convulsions. Disorders of vision and hearing, with intense pain in the occipital region, developed. The epileptic attacks became more prolonged, the convulsive part being more prominent than in ordinary epileptic convulsions. A condition of semi-stupor and then of coma followed, and finally death occurred. At autopsy a glioma was found in the right lobe of the cerebellum.—*Journal of Nervous and Mental Disease.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE NEW SESSION; NOTES ABOUT THE INTRODUCTORY ADDRESSES, ETC.—MANCHESTER INFIRMARY — RECENT DEATHS.

London, October 3.

The one event of the week is, of course, the opening of the winter session, and the one subject of our conversation refers to some phase of the celebrations. The addresses to students still maintain their position in some schools, though the number who are going over to dinners and *conversazioni* rather increase. As to these introductory lectures, the importance, or rather the necessity, of cultivating the faculty of observation occupied a prominent place in several. Students were charged to see for themselves; to observe carefully and accurately, and assured that accuracy of observation would do more to promote their progress than much book learning. Not that books are to be neglected, but reading without personal observation cannot make a safe or successful practitioner.

Side by side with the introductories at our hospital schools, may be mentioned the address at the Birkbeck Institution, delivered by Sir A. W. Rücker, principal of the reorganized London University. He remarked that the founders of the Birkbeck were, practically, the founders of the University. The most salient feature in the reorganization of the University was that the undergraduates were of two classes, external and internal, and this would be maintained, as it would be a mistake to fritter away the distinction between external and internal degrees.

The reorganization had been, in part, caused by the overpredominance of examinations in English education. He might well have added that the London University had been the greatest sinner in this respect. He did not, but he went on to say that more liberty is henceforth to be given to teachers, and examinations are not to be the only test of the alumni. He professed, on the part of the University, the most earnest desire to make arrangements as convenient as possible to both teachers and students.

To return to the medical addresses, Mr. P. Fleming, at University College, reviewed the various classes in the curriculum, and showed the value and place of lectures, as supplementing and guiding study by books. Practical anatomy, he said, brought out patience in investigation, accuracy in observation, and developed the critical faculty more than physiology. Students should become their own teachers as much as possible, striving to weigh the value of the facts under their notice. They should work in the scientific spirit—that is, a spirit always seeking truth, contented with nothing less than truth, ready always to speak truth, and, if necessary, to suffer for truth. A spirit of indolence or routine was opposed to all this.

Mr. Stephen Paget gave the address at the Middlesex Hospital, and compared the advantages of that school to the universities. He declared the hospital deserved better than any university the name *alma mater*, for her motherly kindness was not limited to her own sons and daughters, but extended every year to 4,000 in- and 49,000 out-patients. The medical profession was the one whose students were actively and constantly employed in doing good to other people. By this sort of life they learnt, as nothing else could teach them, to understand their fellow creatures. They need not go elsewhere to see how the poor of London lived, and how drink, preventable disease, the sweating system, immigrant aliens, and dangerous trades thinned their ranks. As for the curriculum, no one could say it was not liberal, for it was colossal; it would be hard to find a wiser or wider plan of work at Oxford or Cambridge, or, having found one, to find many students there able to live up to it.

At St. George's Hospital Dr Whipham took as his text the late Sir W. Gull's remark that "in medicine we make more mistakes by not looking than by not knowing;" and from this went on to show how important is the power of looking. Not only the disease, but the patient must be observed. Unless the power of observation were cultivated, a practitioner would hardly meet with any success.

The London Hospital, Bart's, and St. Thomas's have forsaken the introductory lecture, and content themselves with dinners, etc. At Charing Cross Hospital the Huxley lecture now marks the opening session, and this year it was given by Professor Welch of John Hopkins University, who took for his subject "Immunity."

Some of our London men went to the provincial schools. Sir H. G. Howse, President of the College of Surgeons, who went to Sheffield, talked about the relation of medicine to religion, and the conformity of moral to natural law in a way which, judging from a report, would, I should think, tend to obfuscate rather than enlighten the students. Incidentally, he said if the General Medical Council should ever remove Latin from the preliminary examination, he would advise them to acquire, at least, an elementary knowledge of it.

Sir. D. Duckworth gave the lecture at Manchester, and discoursed pleasantly on knowledge and wisdom in medicine. He also pleaded the claims of a wide, general education, founded on the *literæ humaniores*, and repudiated the notion that science alone could be as good an agent for securing mental width and culture.

At Guy's Hospital the Lord Mayor attended in full state] and distributed the prizes. He congratulated the recipients, and urged the claims of hospitals for support, enforcing his remarks by reference to the King's efforts on their behalf.

At the Women's Medical School the Treasurer of the Royal Free Hospital addressed the students, and congratulated them that the doors of great institutions were steadily yielding to the pressure of women. He announced that the Obstetrical Society had admitted women, and three ladies connected with the school had been elected. This does not seem much of a concession from the council who have made themselves patrons of midwives as an inferior grade of the profession.

At the Royal Veterinary College Professor Bottomley, M.A., urged the claims of science on the government. British practitioners could hold their own, as practical men, but they had not the opportunities for research which the foreigner enjoyed in State-equipped laboratories. It was not lack of brains that kept them back, but lack of opportunities which government ought to supply, for, as Ruskin said, "Knowledge is the true wealth of the country."

An alarming fire occurred at Adenbrooke's Hospital, Cambridge, on Wednesday afternoon. The roof of one ward was destroyed, and great damage done to the ward underneath it. All the patients were safely removed, but there were distressing and exciting scenes, and one fireman was injured.

Among public bodies received by the new Lord Lieutenant of Ireland (the Earl of Dudley) were the Royal Colleges of Physicians and Surgeons, when his Lordship took the opportunity of paying some pretty compliments to the medical profession.

The Manchester Infirmary question has been advanced a step. The trustees have determined not to rebuild on the present site, and a practically new board of management is about to be elected, most of the members of the former board having resigned.

Among recent deaths I notice that of Dr. A. B. Blacker, Superintendent of the *X*-Ray Department at St. Thomas's Hospital. He was only forty years of age. He had published several contributions on light as a therapeutic agent.

Mr. A. G. Field, F.R.C.S., died on the 29th ult., aged eighty-two. He was formerly surgeon to the Sea Bathing Infirmary and to the Brighton Hospital.

Henry Wright, J. P. of Scarborough, died suddenly on the 29th ult., aged seventy-six. While sitting in his chair in the evening, he became unconscious, and his medical friend, on arrival, found life extinct.

The deaths are also announced of Colonel Carew, D.S.O. of the R.A.M.C., aged sixty-one, who was P.M.O. in the Tochi field force, 1897-1898, and held medals and clasps. Brigade-Surgeon C. W. Watling, A.M.S., is also dead, aged sixty-eight. He was in the Afghan War, 1878–1880, and the Nile Expedition, 1884-1885, for both of which he held medals and clasps.

LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

AUCKLAND, September 18, 1902.

I BELIEVE that it is written in the history of the United States that on one occasion the Governor of North Carolina said to the Governor of South Carolina, "It is a long time between drinks." Changing the last word, the remark is applicable to my letters during the past few months. The explanation is not that I have nothing to write about—the materials have been abundant—but but that having been, since March 19, an officer of His Majesty's Imperial Auxiliary Forces (!), I am forbidden, by the King's regulations for the army, "to publish or communicate to the press any information, without special authority, either directly or indirectly. They will be held responsible for all statements contained in communications to their friends, which may subsequently be published in the press. They are not to attempt to prejudge questions under investigation by the publication, anonymous or otherwise, of their opinions, and they are not to attempt to raise a discussion in public about orders, regulations, or instructions issued by their superiors." Par. 423, King's Regulations for the Army.

This very comprehensive rule prevents me from writing anything about the Army Medical Corps with which I have been connected since March last. I may say, however, that a vacancy having occurred suddenly among the surgeons of our Ninth Contingent, I was asked twenty-four hours before the transport had to sail whether I would go. I had only two minutes to make up, what I suppose I must call my mind, and, forgetful of my seventy years and their attendant infirmities, I foolishly consented to take the appointment, and went to South Africa. It was as Kipling sings, "Back to the army again, sergeant!" I had the two medals and Sepastopol clasp for the Crimea, and a silly desire to have a third medal for South Africa had much to do with fixing my resolution. Had I known all the miseries I had to endure from asthma and insomnia the G.C.B. would not have tempted me. However, there is much that I learned which I could have learned in no other way, and I have, I believe, the distinction of being the only man in His Majesty's service entitled to wear the Crimean and South African medals.

There has been much sickness on board the transports bringing back our contingents and those from Australia to their homes. A Royal commission has been sitting here, and another in Sydney, N. S. W., to investigate the causes of the extraordinary sickness among a lot of healthy, or apparently healthy, young men. One ship, in which I came over from Durban, not on duty, but invalided, lost nineteen by death out of about a thousand troops. Two of these died at sea, and seventeen soon after landing from measles and pneumonia. When landed, they were no longer under military surgeons, but under the Health Department, and, therefore, I am permitted to say that the selection of a quarantine station for these men was a most unfortunate one. A bleak, dreary island, with very imperfect hospital appliances, was about as bad a place for measles as could be picked out. What the finding of the Commission may be will not be known until their report is published, and as the evidence was all taken in camera, all judgment must be suspended until it is published.

Attention has recently been called by the Board of Education to the extraordinary amount of sickness among the teachers in our public schools, involving long leave of absence, say three to six months. As they are only paid for one month, it is evident that this long leave must be urgently required. Having had a large number of teachers under my own care, I should attribute the causes of their illness, first, to excessive bodily fatigue, caused by standing or walking about during the whole of the school hours, and, second, to the nervous anxiety and worry about the result of the examinations, and the inspector's visit and report. I have visited schools, and I am surrounded with young people who have been entirely educated in our public schools, and for the life of me I cannot see what experienced teachers should have to worry about. The modicum of knowledge imparted in our schools is so extremely minute, the boy or the girl emerges from them so thoroughly stamped as belonging to the uneducated classes, that if, instead of being taught by trained teachers, who have all undergone a vigorous examination, they had only passed through a dame's school, I cannot see what the difference would have been. Yet the teachers, the women especially, simply worry themselves to death about these wretched children.

The winter here has been miserably wet and cold. How different from the glorious climate of Natal, where hardly any rain falls during the winter, and you have bright sunshine with a clear blue sky during the day, warm enough in midwinter to dispense with a fire, and only requiring one at night. I enjoyed better health during the latter part of my stay in Natal than I had for twenty years. Here, a vast number of old people have been carried off, and bronchitis, etc., are very prevalent.

DHOBIE ITCH.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In your number of September 13, 1902, my attention was attracted by an article on "adobe itch." The writer was evidently referring to that tropical disease known as "Dhobie (laundryman's) itch," from the idea that it was spread through the uncleanly habits of the "dhobie," or washerman. The term is applied to almost any form of intertrigo, is an epiphytic disease, and is usually caused by one of the trichophytous microsporous, or the germ of pemphigus contagiosus. When I left the Philippines about a year ago, it was very far from disappearing. It has been brought to this country by soldiers returning from the Philippines, and is now very common at this post.

CHAS. F. MASON, M.D.,
Major-Surgeon, U. S. A.

FORT SAM. HOUSTON, TEX.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 16, 1902

Pelvic Cellulitis as a Complication of Uterine Fibroids—A. T. Cabot reports two cases of death after hysterectomy for fibroids, in both of which the same complicating condition existed; namely, a cellulitis of the pelvic wall, which, when awakened to activity by the operation, led rapidly to a fatal issue. There was no evidence of sepsis introduced at the time of operation, and the author is left with the belief that in both cases an inflammation already existed in the pelvic wall outside of the peritoneum He concludes that it is wise, in any case of hysterectomy for fibroids that are or that have been recently inflamed, to inspect the pelvic wall with great care to see if any swelling or induration can be discovered. This search should be directed especially toward the base of the broad ligaments, where they spread out on the pelvic wall, and where their lymphatics enter the glands that lie along the iliac vessels. The sudden appearance of a highly septic condition immediately after a clean operation should strongly suggest the condition above described, especially if there was sloughing or abscess formation in any part of the fibroid removed.

X-Ray Treatment of Malignant Disease.—Seabury Allen reports a series of cases with photographs illustrating the *x*-ray treatment of malignant disease. Two of them had epidermoid cancer, and both had been advised against operation. In one of twelve years' duration, after a month's treatment with a total exposure of three hours and twenty minutes, there is a perfect result, and no recurrence after five months. One man had an epithelial cancer of twenty-five years' duration, involving the nose, cheek, forehead, and parts about the eyes. Treatment of two hours and twenty minutes' total exposure resulted in a cure. Walter J. Dodd reports the case of a woman suffering cancer of the breast which had recurred after operation. She was taking twenty-five grains of morphine a day to relieve the pain. The tumor is now one-half its former size, though still very tender. The pain was relieved after five exposures, recurred when treatment was stopped, and ceased again when treatment was resumed. At present she uses only two grains of morphine a day. James C. White says that in cutaneous tuberculosis the effects of the *x*-ray treatment are slowly favorable, but in cutaneous sycosis it works like a charm. In four cases which had been under treatment for nearly a year, by ordinary remedies without yielding, six exposures to the *x*-ray caused great improvement within a few weeks, and in two cases the disease was cured. In cases of alopecia areata the treatment is said to have restored a growth of hair, yet, curiously enough, it is also used to remove hair from women's faces.

Journal of American Medical Association, October 18, 1902.

Excision of the Gasserian Ganglion.—J. B. Murphy and J. M. Neff report ten cases operated upon by the Hartley-Krause method. They enumerate the indications for the operation to be as follows: (1) When all internal medication and the removal of external irritants have failed. (2) When all branches of the nerve are involved in the pain. Here it should be a primary operation. (3) When individual branches only are involved and relief has not been secured after the peripheral operation. (4) In cases in which formerly divisions at the base were indicated.

Infrapubic Section for Prostatectomy.—E. W. Andrews offers the following conclusions: (1) The narrowness of the male pelvic outlet becomes surgically important with the overgrown prostate. (2) Overgrowth of prostate does not cause obstruction unless there is also outside pressure. (3) This may come from the ligaments and muscles without the organ actually pressing upon the ischia or from bony pressure. (4) Relieving the prostate from the fixed space behind the pubis allows it to expand and cures the obstruction. (5) This can be done best by an anterior incision and should be accompanied by a cutting of the prostatic ring and removing a segment extraurethrally. (6) Incidentally, the change of position, lowering the bladder outlet, does away with the retroprostatic pouch, and greatly assists natural drainage. (7) The separation of the prostatic and urethral ligaments from the pubis, and the weakening of the urogenital diaphragm is not to be avoided, but sought.

The Disappearance of Opacities of the Crystalline Lens.—The views of W. L. Pyle are summarized as follows: (1) There is no question as to the authenticity of many reports of the spontaneous disappearance of senile cataract, and these cases may be explained and classified in five groups, as follows: (*a*) Cases in which there was absorption after spontaneous rupture of the anterior or posterior capsule; (*b*) cases in which there was spontaneous dislocation of the cataractous lens; (*c*) cases in which there was intracapsular resorption of the opaque cortex and sinking of the nucleus below the axis of vision after degenerative changes in Morganian cataract, without rupture of the capsule or dislocation of the lens; (*d*) cases in which there was complete spontaneous resorption of both nucleus and cortex without reported history of ruptured capsule, dislocation or degenerative changes of the Morganian type; (*e*) cases of spontaneous disappearance of incipient cataract without degenerative changes or marked difference in the refraction. (2) It is not uncommon for opacities of the crystalline lens or its capsule, the result of traumatism, to disappear, even when the capsule has been penetrated. (3) Too much stress cannot be laid on the value of personal hygiene, treatment of associate local and general disorders, careful and repeated refraction, and the proper use of the eyes in arresting the progress of incipient cataract. (4) In certain complicated cases, secondary to grave nutritional disturbances, lenticular opacities may entirely disappear under appropriate treatment. (5) Generally speaking, the so-called "non-operative" treatment of cataract, as practised by advertising charlatans and irregular physicians, is worthless, often distinctly dangerous, and consists in no beneficent measures not known and appropriately used by all reputable oculists.

Endocarditis as a Complication of Pneumonia.—E. F. Wells summarizes his views in the following propositions: (1) Endocarditis is an infrequent occurrence in pneumonia, and ulcerative endocarditis is a rare event. (2) When endocarditis occurs it does so comparatively early in the pneumonic attack, and ulceration may occur at any time within a period of probably several weeks, the time of embolic showering being possibly coincident with some unusual valvular strain. (3) The symptoms and signs, previous to ulceration or in the cases in which this does not occur, are equivocal. (4) Any of the valves may be affected, but the preference is for the mitral, although the aortic is oftener attacked than in any other form of endocarditis. The vegetations are quickly formed and massive, and they have a marked tendency to ulcerate. Pneumococci are present early, and should ulceration occur, the blood becomes infected. Later the pneumococci die and embolic showerings are sterile. (5) In simple endocarditis the diagnosis is always difficult and often impossible. The murmurs and embolic showerings of ulcerative endocarditis render the diagnosis of this condition comparatively easy. (6) The prognosis of simple endocarditis is not well established, but that of the ulcerative form is extremely grave, although not absolutely hopeless. (7) The treatment of pneumococcal endocarditis, both simple and ulcerative, should embrace, as a cardinal and the most important principle, absolute rest in the recumbent posture, thus placing the least possible burden on the heart. (8) There is but little tendency toward cicatricial contraction, and when recovery ensues, even in cases with ulceration, the integrity of the valve may be unimpaired, and health completely restored.

Medical News, October 18, 1902.

Recent Discoveries in the Domain of Etiology.—D. H. Bergey states that the investigations upon the etiology of yellow fever are practically conclusive in demonstrating that yellow fever is due to an animal parasite, transmitted in a somewhat similar manner to the transmission of malarial fevers. The direct causative agent of the disease has not yet been discovered. The writer's own investigations upon variola and vaccina have led him to believe that variola is caused by an animal parasite belonging in the class Sporozoa, and that vaccina is due to a modified form of the same parasite. The parasite of variola is probably transmitted through the air, or by direct contact, as in many bacterial diseases. There is no evidence that insects play any part in the dissemination of the disease, except that flies may carry the infectious agent on their bodies from contact with cases of variola. The organism of "spotted fever" is a hæmatozoon, and is found in the red blood cells in the circulating blood, but more abundantly in the blood cells in the congested capillaries of the tissues. No pigment was found in the organism, and so the discoverers believe that the parasite belongs in the class with the Texas-fever organism, and not with the malarial group. The tick is believed to convey the parasite.

Polyhydramnios Its Differential Diagnosis and Treatment, with the Report of Cases.—Edward P. Davis defines polyhydramnios as a condition of more than two pints of amniotic liquid at full term. The pathology is not fully known. Many conditions accompany polyhydramnios. In making the diagnosis, the condition of pregnancy must first be determined; then, in polyhydramnios, evidence of faint uterine contraction can usually be obtained, while the finger can often be inserted into the cervix and a presenting part felt. Ectopic gestation must not be forgotten. In ovarian cyst the illness is longer, and the swelling at first unilateral. The uterus is but little enlarged, and there is no intermittent hardening of the tumor. In ascites the dulness changes with the alteration of the patient's position. When pregnancy is discovered, then the presence of other complications must be recognized or eliminated. Treatment by drugs is valueless. When polyhydramnios is slight, and the patient's health good, pregnancy should not be interrupted. If interference is indicated from rapidly increasing distention, and impairment of the patient's health, the membranes should be ruptured, and the fluid be allowed to escape gradually till the presenting part is fixed against the cervix. Firm pressure is exerted on the abdomen by a binder. Labor should be carefully watched, as the fœtus may assume faulty positions. Labor should not be hurried, for the child's sake, as the fœtus is frequently deformed. The uterus should be completely emptied and caused to contract.

New York Medical Journal, October 18, 1902.

A Case of Acute Diabetes in a Child Three Years of Age.—The case is reported by F. B. Swartzlander, who was called only three days previous to the patient's death in coma. The family history was non-significant. About six weeks before death the child had an attack of indigestion, but seemed to recover therefrom. An intense thirst and frequent desire to urinate developed, together with anorexia and slight emaciation. A full-sized chamber would not hold all the urine passed at night. Three liters 400 c. c. were voided in one period of twenty-four hours. It contained sugar, 3.2 per cent.; no albumin; specific gravity, 1048. Diacetic acid was present in considerable quantity. Lungs were normal, heart showed a slight anæmic mitral murmur. Early in the morning of the fourth day of observation, she became comatose. The extremities were cyanotic and cold; reflexes nearly absent; pupils dilated, failing to react to light; breathing was labored and stertorous; and the pulse so weak it could not be counted. The acetone odor was very evident. This condition lasted five hours, and she died, the respirations growing gradually more shallow until they ceased.

The Clinical Value and Treatment of Atonic Dilatation of the Stomach.—B. C. Loveland finds, as a common clinical condition in this class of patients the following: A feeling of weight, or fulness, in the region of the stomach, gas, distress, not to say pain; appetite variable and irregular, often great fear of taking even wholesome food on account of expected distress; a muddy complexion, tongue more or less coated, often flabby and indented with the teeth, possibly surmounted by inflamed or congested papillæ; constipation, and frequently associated intestinal indigestion, a tendency to scantiness and high color of the urine; restlessness at night, especially toward the early morning hours. Careful examination will show, not only an enlarged gastric area, but often a loose kidney, displaced transverse colon, and, in women, frequently a prolapsed uterus. Analysis of stomach contents is not necessary or expedient in most of these cases if other methods of investigation are used carefully, but, when resorted to, the gastric secretions will usually be found normal. Treatment calls for regulation of clothing, habits, bathing, and exercise. Faradism over the stomach and bowels may be of service when the symptoms are mainly local. Neurasthenic symptoms indicate spinal galvanization. A free diet is prescribed, water and milk if the patient requires more flesh, and, if necessary, frequent feeding. Among drugs, the first is nux vomica or strychnine, to which may be added rhubarb, if a constipated tendency exists; β-naphthol and bismuth subgallate, if gas or intestinal fermentation is a prominent symptom; and, in lithæmic subjects, sodium salicylate, given in a copious draught of water between meals, will often be of great advantage.

Observations on Muscular Relaxation in Its Relation to Women's Diseases.—D. E. Walker believes that this condition is often overlooked as a cause of disease, and that relaxations of the abdominal wall and pelvic supports, together with displacements of the abdominal and pelvic contents and dilatations of the stomach and large intestine, have often been responsible for symptoms erroneously ascribed to organic pelvic disease. In the relaxed vaginal outlet we find a muscular relaxation, and a definite causative factor therefor in the subinvolutions following confinement or miscarriage. But there are patients presenting relaxed pelvic tissues and uterine prolapse who have never been pregnant. It is often difficult to assign a cause for the general muscular atony. It may follow overexertion and injuries, as well as child-bearing, with all its sequelæ. All patients presenting it do not necessarily suffer, for some establish a tolerance for the condition and some are hypo-sensitive. Local atonic conditions are seen in the vagina from the frequent use of the warm douche. It is also the author's belief that muscular relaxation enters largely as a causative factor into those non-inflammatory pelvic troubles of women which fall under the head of granular erosions, congestions, retropositions, prolapses, menorrhagias, metrorrhagias, dysmenorrhœa, and also of subacute endometritis. Bearing in mind the pelvic blood supply, one can readily see how relaxation of supports first brings about a sagging of the pelvic contents, then interference with the return flow of the blood, and a consequent congestion and increase in size and weight, with displacements of uterus and ovaries, and interference with the functions of menstruation and defecation. Then come menorrhagia, dysmenorrhœa, endometritis, and constipation, with any or all of their attendant ills. A common symptom in many of these cases is pain at the inguinal rings from traction on and tiring of the weakened round ligaments.

American Medicine, October 18, 1902

Pericarditis as a Terminal Infection of Chronic Bright's Disease.—Herman B. Allyn calls attention to three important physical signs of pericarditis with effusion: (1) Dulness in the fifth interspace to the right of the sternum. (2) Fluoroscopic examination is as helpful in pericardial effusion as in pleural effusion, and is very important, The opaque area does not pulsate as it would in aneurysm or enlarged heart, and the upper level can be seen to move with change of posture of the patient. (3) Pulsation of the vessels of the neck may be as marked as it is in aortic disease, and may be accompanied with capillary pulse. The most certain method of discovering the presence of fluid is by exploratory puncture with an aspirating needle. The duration of this kind of pericarditis is short. The prognosis of the pericarditis of chronic Bright's disease is practically always fatal. The recognition of the pericarditis is of greater importance in the prognosis of the venal affection than in the treatment of the pericarditis itself.

Chronic Ulceration of the Leg Treated with X-Rays and "Brush Discharge."—W. L. Heeve declares that in using the "brush discharge" the indirect method should be employed. The electrode is attached by a chain to the gaspipe and held at the extreme end of the handle. By this means the discharge is powerful but not painful. The treatment will improve circulation, increase nutrition, reduce œdema, and rapidly heal ulcers. By this treatment the writer has cured twenty-four cases of chronic ulceration; two, due to traumatic causes, had passed into the chronic stage on account of neglect; three, traumatic, resisted all medical treatment on account of the old age of the patients; nineteen were due to varicose veins. In the treatment the tube is placed at a distance of about eight inches, and so that the platinum anode plate is in the proper obliquity to reflect the rays upon the ulcer. The tube should be of medium vacuum, and actuated strongly. The duration of exposure should be from ten to fifteen minutes. At least seven days should elapse between the first and second exposure, and five days between the second and third. After the fourth exposure, which should never be before the fifteenth day, the part should be "rayed" every third day until healthy granulations begin to form at the base. Then the "brush discharge" from a static machine is begun. This must be applied over the ulcer and surrounding part, and in cases in which varicose veins are the exciting cause, along the entire leg and thigh. Each treatment must be twenty minutes in duration.

Types of Infection Produced in Man by Intermediate Members of the Typhoid-Colon Group of Bacilli.—Warren Coleman in this paper speaks of the psittacosis type. He defines psittacosis as an infectious disease of special type, transmitted to man by parrots (hence the name) affected with the same disease. The bacillus psittacosis was discovered by Nocard in 1892. It is an intermediate of the typhoid-colon group. It is pathogenic for man, and retains its virulence for a very long time. Infection in man may occur directly from the affected bird, from inanimate objects, as cages, or from man to man. Women suffer more often than men from the disease. The parrot is the only animal known from which man has contracted the disease. There are several clinical forms: mild, ordinary, pulmonary, and adynamic. Death from uncomplicated psittacosis is rare. The serum of animals immunized with bacillus psittacosis agglutinates this bacillus strongly. It also agglutinates bacillus typhosus in low dilution (1:10). Clinically, the disease is most easily mistaken for typhoid fever. According to the French observers, the points of difference are the suddenness of the initial rise of temperature and the abrupt defervescence, the early appearance and intensity of the respiratory troubles, and the absence of eruption. Also when diarrhœa is present it does not possess the typhoid characters. There is a strong resemblance between grippe, especially when complicated by pneumonia, and the pulmonary form of psittacosis.

Philadelphia Medical Journal, October 18, 1902.

Acroparæsthesia.—Frank R. Fry runs briefly over several cases of this kind. He states that there is a relation between paræsthesiæ of all kinds to the neuropathic predisposition, and, as a rule, they are the most pronounced and emphatic when this tendency is the greatest. The lithæmic tendency also contributes to their appearance. We do not know the relation of the the lithæmic to the neuropathic tendency, except that they are so frequently associated with each other. Practically, we know nothing about the pathology of acroparæsthesia. Usually a case of this kind reveals its nature, and if it is studied, it will finally not be confused with Raynaud's disease, neuritis, myelitis, or hysteria. It is one of the refinements of the neurologist's art to calculate the value of symptoms in the most neurotic classes of patients.

Hodgkin's Disease; with the Report of a Case.—Thomas C. Ely, from his study of this subject, presents the following conclusions: As to the question of Hodgkin's disease being of tuberculous origin, there is circumstantial evidence in the fact that the lymph glands are one of the most frequent seats of the tuberculous process. In Hodgkin's disease the process begins as a purely local disease, in a gland or chain of glands, and seems to extend by spread of germs, just as we may expect of the tuberculous processes. Cases in which there is an abraided surface of the skin or mucous membrane, which seems to be the starting point of many cases of Hodgkin's disease, may be explained by the fact that tubercle bacilli pass through the skin, without lupus or tuberculous skin inflammation and, not finding in the skin a favorable soil, pass on to neighboring glands of the neck or axilla in a predisposed individual. If inoculation experiments only were regarded as proof, Hodgkin's disease might, perhaps, be added definitely to the list of diseases of tuberculous origin. Only inoculation experiments with the suspected gland itself seems positive proof. Clinical observation, and even autopsy, with most careful histological and microscopical examination, has not unearthed the cause. Many histological changes found at autopsy are undoubtedly due to secondary infection with secondary inflammations, which must give a great diversity in the anatomical picture, and which emphasizes the necessity for inoculation proof. Hodgkin's disease differs in its final stages from the classical tuberculous glands, those of the latter being cheesy degeneration and tuberculous ulcers. In the fibroid glandular inflammation of Hodgkin's disease, the deficiency of blood vessels, and consequent deficiency of nutrition, which causes this coagulation necrosis in the former instance, may modify the the result in the latter, the cause being the same. Whether the glands shall suppurate and caseate, as in classical tuberculosis, or become fibroid, as in Hodgkin's disease, is determined not so much by the character of the microorganisms, nor by the virulence of the toxin, as by the nature of the lymphatic system itself, by hereditary or by an acquired cause. A uniform anatomical basis for a definite decision of tuberculosis seems to have never been possible, and all classifications of glandular diseases as tuberculous or otherwise without inoculation experiments must be regarded as incomplete.

The Lancet, October 11, 1902.

Explosive Eructations.—A. A. Martin reports the case of an elderly man with atonic dyspepsia, who suffered greatly from eructations "tasting like rotten eggs." On one occasion, two hours after eating, he was obliged to belch just as he was lighting his pipe with a match; instantly there were a blinding flash and a slight report, due to ignition of the gases released from the stomach. The patient's beard and eyebrows were thoroughly singed, but happily no further damage was done.

Rats and Plague.—G. J. Blackmore gives brief notes of each of thirty-three cases of the disease, showing that, in all probability, rats were the medium of contagion. Relatives of patients did not contract the disease. "Contacts" did not contract the plague. Neighbors of patients did not and while the houses of the patients were widely separated, all the latter worked in the same rat-infected area. It is believed that the human flea is probably the intermediate carrier of contagion from man to man, and the rat flea from rats to man. It is stated that the rat flea will not bite human beings, but the evidence in support of this contention is slight and inconclusive. The fact that in one or two cases it has been found that the rat flea will not attack man is no proof that it never does so, and the evidence which seems to show that it is only occasionally that this particular flea attacks men—and then only certain individuals—accounts perfectly for the fact that in plague due to rat infection only a limited number of persons are attacked in proportion to the number of rats suffering from the disease. It is stated in a recent and authoritative book on the dog that the dog flea never attaches itself permanently to man, although it may annoy him with occasional visits, and it is extremely probable that the same statement holds true with regard to the rat flea.

Unilateral Pressure on the Thorax as an Aid in Diagnosis.—G. Moreno de la Torre advises the use of the following procedure in diagnosticating pneumonia, provided pain be present, no matter how vague or abnormally situated the latter may be. If both hands are applied over one side of the chest in front and pressure sufficient to arrest all movement in the subjacent lung be slowly exerted, when the inflammation causing the pain is in that lung the pain will either disappear or, in the event of it persisting, the patient will at least breathe without discomfort. If there be inflammation in the other lung also, the pain will generally continue, though its character and seat may change. If the inflammation is in an abdominal organ, or the tissues surrounding it, the pain will continue and will, perhaps, increase. By making pressure first on one side of the thorax and then on the other, it may be possible to draw conclusions as to whether the part effected is in the thorax or the abdomen, and in the former case, on which side of the thorax it is. If pain referred to the abdomen disappears when pressure is made on the thorax, the inference is that the primary cause of it is some pulmonary disorder.

A Case Illustrating the Local and Pulmonary Effects of Abdominal Pressure.—The patient of R. Knox was a girl of twenty-one years, with left-sided pleuritic effusion. Later an effusion appeared in the abdomen. Adhesive plaster, in strips two inches broad, was applied to the abdomen, several layers being used, until a fairly rigid casing of the abdomen was obtained. The pressure was moderate at first. The strapping was applied all over the abdomen, extending up to, but not involving, the lower ribs, so as not to interfere with respiration. Tonics were given and fresh air, with nourishing food, was ordered. The strapping was removed in three days, and the fluid was found to have diminished in quantity, when the abdomen was restrapped, more pressure being applied on this occasion. The treatment was continued for about three weeks, each application of strapping being allowed to remain for three or four days. The fluid gradually disappeared, and, on removing the last strapping, the abdomen presented a normal appearance. The case was regarded, from its history and clinical course, as being of a tuberculous nature. Assuming this diagnosis to be correct, the author regards as of special interest the following points: (1) The great value of firm abdominal strapping as a means of promoting the absorption of an excessive quantity of free fluid in the peritoneal cavity. (2) The rapid absorption of the fluid which had resisted for months the ordinary medicinal treatment. The improvement was noticed after the first application of strapping, and gradually increased with each fresh application, till, in three weeks, the peritoneal cavity was cleared of all fluid. (3) The resulting improvement which took place in the lung condition, the resonance of the lung improving and respiratory sounds in the affected area becoming more evident. The absorption of the fluid in the peritoneal cavity was aided by the firm pressure forcing the fluid upward toward the diaphragm, which is liberally supplied with lymphatic structures. The strapping helped to restore the power of the lymphatics, and to give the necessary support to enable them to deal with an abnormal accumulation of fluid.

British Medical Journal, October 11, 1902.

Puerperal Eclampsia in the Light of Thyroid Inadequacy and Its Treatment by Thyroid Extract.—H. Oliphant Nicholson believes that it is not improbable that the occurrence of many cases of puerperal eclampsia is closely connected with inadequacy of the maternal thyroid system—thyroid and parathyroid glands. In some cases of pregnancy a deficiency of iodothyrin is established, and this leads to the formation of a "vicious circle," and there exists a condition of eclampsia. Thyroid extract is beneficial in all cases of eclampsia, but when convulsions are severe and frequent, at least one large dose of morphine is indicated. Saline infusions may also be given to accelerate the re-establishment of diuresis. When the patient is dying from coma, or with a rapidly rising temperature, a cold or tepid bath seems to offer the best chance of recovery. In the comatose type morphine is not given. The writer suggests the trial of thyroid extract in some of those rare cases of suppression of urine which occur after labor and miscarriage.

A Case of Intermenstrual Dysmenorrhœa (Mittelschmerz) Cured by Successive Oophorectomies.—R. H. Anglin Whitelocke describes an interesting case of a woman of twenty-six who suffered severe intermenstrual pain, which began exactly ten days before the flow, whether she was regular or not. The administration of drugs and cervical dilatation failed absolutely to give the patient any relief. Operation was performed in the hope of relieving the patient. The abdomen was opened in the middle line. The left ovary was enlarged and cystic, and was removed with the Fallopian tube. The right ovary was of natural size, but showed two tiny cysts, which were punctured. The uterus was enlarged and smooth. Although the pain was slightly less, it still continued, and finally another operation was performed, and the right ovary and tube were removed. In eighteen months it had become cystic, and was as large as a small orange. A small myoma was seen in the fundus of the uterus. Since the last operation the patient has never suffered the least pain. Menstruation has ceased, and the uterus has shrunk almost to its normal size, and the patient is doing hard work. In all probability the fibroid had more to do with the matter than the cystic degeneration of the ovaries. Histologically, the ovaries showed nothing peculiar.

Concerning Spastic and Syphilitic Spinal Paralysis.—Wilh. Erb presents this paper. Spastic spinal paralysis—primary spastic paraplegia—is much rarer than tabes, and begins and progresses slowly. The writer knows of a case which has already existed for twenty-six years without undergoing any change at all. The characteristic symptom-triad is weakness, muscular rigidity, and exaggerated tendon reflexes. The diagnosis is very simple, as a rule, when these symptoms are remembered. Multiple sclerosis is the only one disease which sometimes causes much difficulty. To the symptoms just enumerated should be added the pathological plantar reflex, recently described by Babinsky. The etiology is still completely in the dark. Syphilitic spinal paralysis presents a strong resemblance to spastic spinal paralysis. It occurs almost exclusively in individuals previously suffering from syphilis. It often occurs from two to six years after syphilitic infection, but may develop much later. Besides the typical picture of spastic spinal paralysis, there is always a disturbance in bladder function and a usually slight, but always demonstrable, subjective, and objective disturbance of sensation. The onset is usually quite chronic. The prognosis is not altogether unsatisfactory. Energetic and repeated treatment with mercury and potassium iodide is essential. In addition, the usual treatment of spastic spinal paralysis is necessary—strychnine, hydropathy, electricity and massage.

The Huxley Lecture on Recent Studies of Immunity, with Special Reference to Their Bearing on Pathology.—William H. Welch includes under "Studies of Immunity" investigations concerning the specific properties of cells and fluids in health and disease of the widest interest biologically. This field shows how interdependent are the sciences. He speaks of Metchnikoff's work, and believes that he has defended his phagocytic theory with a large measure of success. Whatever one's attitude toward this theory, one must admire the number of new facts which he has presented, and his skill and fertility of resource. Nuttall's work has been most important with regard to the antibacterial properties of the body fluids, especially the blood serum. Buchner and others have gone on also in this line of research. Pfeiffer contributed valuable work, while Behring discovered the fact of antitoxic immunity and the protective and curative value of antitoxin serum. Ehrlich, as well, did much to make these facts clear. Recent work has separated certain specific antibodies into two groups. In the group represented by the antitoxins, the antagonists are single bodies; in the one represented by the cytolysins, the coöperation of two bodies is necessary to produce the antagonistic effect. The two elements which make up a cytolysin are quite independent of each other. Behring well expresses Ehrlich's theory: 'The same substance which, when incorporated in the cells of the living body, is the prerequisite and condition for an intoxication becomes the means of cure when it exists in the circulating blood." Thus we see that there are in the living body substances which may prove its protectors by destroying its invaders, or which may injure it by destroying its own cells, according to the combinations which are formed. The same physiological mechanism is exercised in the production of antitoxins as in the assimilation by the cells of food. There is no reason to believe that there are any special properties in the body for meeting pathological conditions. The writer then touches upon the results which have been attained by the method of serum diagnosis. The most familiar application of this method is the agglutinative test for typhoid fever. It is indispensable in the study of cases of paratyphoid fever. Very interesting work has been done by which differences and resemblances between red blood-corpuscles have been determined by precise quantitive methods. Another interesting line of work has been the study of phylogenetic relationships between animal species, shown by their blood reaction with the specific precipitins. The next subject considered is the bearing of recent studies of immunity on the nature and action of toxins. The great practical problem of bacteriology to-day is to make available to medical practice the bacteriolytic serums, such as antityphoid, antipneumococcus, antistrepticoccus, antiplague, antidysentery serums. At present knowledge of the constitution and action of intracellular bacterial poisons is very imperfect, and cannot yet be applied very definitely to the elucidation of the morbid phenomena of infectious diseases. Welch then presents an hypothesis to explain the source, the method of production, and the nature of certain bacterial poisons. This theory assumes that degenerated and dead bacteria, although recognized as a source of poisoning in infections, are not given the exclusive rôle in this respect. The study of snake venom by Flexner and Noguchi is very important. Their investigations necessitate a very different conception of the nature and manner of action of venom toxins than that previously held. They have taught us that in venom poisoning the substances which are most directly concerned in the act of poisoning are contained in the human and animal body in the form of complements or alexins. The venom is the medium for bringing into the necessary relations with constituents of the body cells, poisons, which are already in the body, or which may be generated there—harmless without the intervention of intermediary bodies. Preston Kyes has positively demonstrated a special class of intracellular complements or endocomplements. This work will probably be instrumental in explaining many morbid conditions. These studies are of great importance in throwing light on various diseases—for example, the group of hemorrhagic infections. The writer says, that although his theme relates especially to the bearing of studies of immunity in pathology, it is hardly necessary to say that these studies were primarily undertaken to elucidate the great problems of predisposition and resistance to disease, and that in this field they have borne their richest fruits. It is very necessary to study systematically the blood and other fluids of the human body in health and disease with reference to their content of specific antibodies, particularly of the bactericidal substances. Recent studies of immunity have brought nearer to a solution the question of the influence of previous disease in predisposing to infection. The investigations concerning immunity have only served to strengthen the foundations of cellular pathology. This knowledge has saved thousands of human lives, and will save thousands more, and to restrict unnecessarily and unjustifiably the practice of the experimental method in these lines is in reality a crime against humanity.

Deutsche medicinische Wochenschrift, September 25, 1902.

Extirpation of a Pseudoleukæmic Tumor of the Spleen.—Erbkam reports the removal of an enlarged spleen, 35 cm. long, 25 cm. broad, and 7.5 cm. thick, which weighed eight pounds. A diagnosis of a pseudoleukæmic spleen had been made previous to the operation, and this was verified by a microscopical examination of the removed organ. The result was extremely favorable. Before operation the patient weighed 116 pounds; within six months thereafter this had increased to 130 pounds. The number of leucocytes was not increased, and the general condition was excellent.

Early Diagnosis of Icterus.—Hamel says that an early diagnosis of icterus may be made by an examination of the blood serum. This takes a decided yellow tint very early in the disease, and before other manifestations are present. For making the examination of the serum the blood (15 to 20 drops) is from a finger-prick into a capillary tube about 10 cm. long; this is then sealed in the flame and allowed to remain in the upright position for several hours until the serum has separated from the clot. In all cases of jaundice the marked yellow color of the serum is then readily apparent.

Intestinal Tuberculous Infection.—A. Heller, to show the frequency of intestinal tuberculous infection, brings forward the following figures: Of 714 autopsies made upon fatal cases of diphtheria, in 140, or 19.6 per cent., there were tuberculous changes present. The lesions showed that in fifty-three, or 37.8 per cent., of these, the tuberculous infection had taken place through the intestinal canal. These figures closely correspond with those recently announced by Councilman, who found tuberculous changes in thirty-five out of 220 fatal cases of diphtheria. Of these, thirteen, or 37.1 per cent., were cases of primary tuberculous infection. Heller has recently observed another case, in a boy thirteen years of age, who died of intestinal tuberculosis. At the autopsy there were found a large number of tuberculous ulcers in the small intestine and cæcum, and also tuberculous changes in the mesenteric glands and liver. From these observations it is apparent that primary tuberculous infection is very much more frequent than is supposed in many quarters.

Berliner klinische Wochenschrift, September 29, 1902.

Action of Alcohol upon Human Metabolism.—Arthur Clopatt, after an extensive series of observations carried out upon a human subject, comes to the conclusion that alcohol after introduction into the body not only conserves the utilization of the nitrogen-free nutritive substances, but also, after the organism has become acclimated to the alcohol, lessens the destruction of the albuminous principles. On the other hand, alcohol exercises no appreciable action upon the absorption of nutritive substances from the intestine.

Obstipatio Spastica.—Von Sohlern considers under this title that form of constipation which is met with in neurasthenic and hysterical patients, and which is frequently associated with ptosis of the abdominal organs. The most diagnostic symptom is the marked stiffening of the intestinal wall, as felt upon palpation. The fæces are dry and hard, and, as a rule, evacuated in small quantities, so that the amount passed bears no normal relation to the amount of nutrition taken. Periods of obstipation, lasting for several days, are of frequent occurrence. Attacks of colic are common, but are not attended by any intestinal fermentation. The keynote of treatment is rest. The patient should be put to bed, and kept there until the action of the bowels becomes normal. Hot abdominal applications are of great service. The diet should be unirritating and nutritious. Water should be given in abundance. Bromide of potash is the drug *par excellence* for this condition, and should be given in good dosage three times daily. During the periods of obstipation enemas of oil and chloral hydrate yield good results. All drastic cathartics are contraindicated, and massage and electricity do harm rather than good. As soon as the bowels have become normal in action the patients may be allowed to go about and gradually resume their ordinary avocations.

Münchener medicinische Wochenschrift, September 30, 1902.

A Peculiar Complication of Pulmonary Hemorrhage.—H. Cybulski reports two cases in which pulmonary hemorrhage was followed by marked dyspnœa and cyanosis. After one or two hours there was coughed up in each instance a whitish morsel, which, upon examination, was shown to be a mass of clotted blood. Following this there was immediate relief to the dyspnœa. The author thinks that dyspnœa following hæmoptysis is frequently due to a similar plugging of the bronchi with blood clots.

Prophylaxis of Whooping Cough.—C. Stamm thinks that greater care should be taken in the isolation of cases of whooping cough. To this end the various departments of health should issue regulations appertaining thereto. These should include the exclusion of children suffering with pertussis from school and all public places. In transporting such children from place to place great care should be observed, and vehicles used for this purpose should be thoroughly disinfected after use.

Spontaneous Recovery after Perforation Peritonitis.—Adolf Weber reports two cases of perforation peritonitis which were not operated upon and in which recovery took place spontaneously. In the first case the perforation was caused by a gallstone and in the second case by traumatism. Both were treated by opium and the local application of cold. The author does not believe that operation should be withheld in this class of cases, but simply reports these instances to show that spontaneous recovery from a perforation peritonitis is not an impossibility

Can Finely Divided Fluids Gain Admission to the Deeper Portions of the Lung by Inhalation.—R. Emmerich, by a series of experiments upon dogs shows, first, that finely divided fluids do gain admission to the deeper portions of the lung by inhalation and, second, that substances present in solution in such fluids after the inhalation of the same may be found in the pulmonary tissue. All of the experiments were carried out by the Bullinger method for producing finely divided fluids. In the first series of tests dogs were made to thus inhale a 2 per cent. solution of boracic acid for one hour. They were then killed and the presence of boracic acid in the lungs demonstrated. The second series was quantitative in nature. Here dogs were made to inhale a 4 per cent. saline solution for one hour The animals were then killed, when it was found that about 1 c.c. of the fluid had gained admission to the bronchi and alveoli As the result of this work there is no doubt but that suitable medication can be introduced into the lungs by the Bullinger method.

French and Italian Journals.

The First Urine of the New-born.—J. Sabrazès has made a series of researches on this subject. Immediately after birth, the infant is excluded from any alimentary influence. It excretes the first urine, which possesses hæmolytic properties; it is very poor in chlorides and in phosphates. Its freezing point is high. At the moment the child is born, it cries, and, in many cases, at the same time urinates. This urine is a transparent liquid of watery aspect, sometimes very slightly lemon-colored, with a neutral reaction or slightly alkaline. The quantity varies between 5 and 8 cubic cm. It is very poor in urea. It contains no albumin. From the work done on this subject, the writer concludes that the fetal kidney secretes, a point which has long been contested.—*Gazette Hebdomadaire des Sciences Médicales*, October 5, 1902.

Nephritis from Mumps.—E. Paganelli reports the case of a boy of nine years suffering from unilateral right parotiditis. The affection was running a normal course, when the author was recalled to the case and found the child almost in a typhoid condition; temperature 39.4° C, pulse 120, respiration 44. There were no symptoms to account for the condition, but on the following day there was œdema of the palpebræ and around the joints, especially those of the hands and feet. Examination of the urine showed a large amount of albumin, with epithelial, hyaline and mixed casts, many white and a few red cells. In six days all untoward symptoms disappeared, and there were merely traces of albumin. The child made a good recovery, There is no doubt that the nephritis was in direct relation with the parotiditis.—*Rivista Critica di Clinica Medica*, October 4, 1902.

Alkaline Extracts from the Organs of Healthy Animals in Their Relation to Immunity toward Anthrax.—F. Tusini has found by practical experimentation, that the effect of the alkaline extract of organs of healthy animals of one kind upon a different species, instead of conferring resistance to the infection of anthrax, actually predisposes to it. In animals of the same species these alkaline extracts have a coagulating action if inoculated in the veins. Extracts of spleen and kidneys appear to have the least influence. Animals inoculated in the veins with extracts from non-coagulating organs furnish a serum whose coagulating powers are lessened as compared with those of normal serum, and whose bactericidal powers are slightly increased. Alkaline extracts of the spleen and kidneys of animals of the same species increase resistance to the anthrax virus.—*La Riforma Medica*, September 24, 1902.

Plastic Operations with the Aid of the Great Omentum.—Achille Sorace has conducted a series of experiments to establish the utility of the epiploon as a means of repairing wounds and the loss of substance in the intraperitoneal organs. It was found best to use the omentum in its entirety, rather than detached strips. The results were as follows: In two cases of parietal resection of the stomach with cauterization of the margins a complete cure followed. In four cases of parietal resection of the small intestines, one simple incision, one cauterization there were five successes, and failure in the sixth case because a detached strip of omentum had been used. On the colon one wound and two resections, all fatal, one because of the use of a detached strip, and the others because of fecal infection of the peritoneum. On the bladder, one case of linear incision, and one of resection of the upper wall with cauterization of the margins—a perfect result. It was noticed that the omentum is not influenced by the gastric and intestinal contents nor by the urine.—*La Riforma Medica*, September 21, 1902.

Extrauterine Pregnancy of Eight Years' Duration; Ablation of the Fetal Cyst.—Condamin reports this case. The patient was married at the age of eighteen, and had a miscarriage six months afterward. In 1893 menstruation ceased and symptoms of a new pregnancy appeared. In July, 1894, labor pains began and lasted four days. They then ceased, but began again two months later, on the occurrence of menstruation. Milk was secreted for four days. The patient recovered promptly, the abdomen remained rather large. In 1895 a surgeon made the diagnosis of fibroma. In 1901 the diagnosis of fetal cyst was made. There was a hard, solid, rounded tumor, which was not painful, on the right side. Operation was performed in 1902. The omentum was adherent to a mass; the appendix was elongated and was resected. The mass was isolated and taken out entire. It contained a fœtus, reduced in volume, but well preserved.—*Lyon Médical*, October 5, 1902.

Society Reports.

THE NEW YORK STATE MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, Held in New York City, October 20–23, 1902.

ALVIN A. HUBBELL, M.D., of BUFFALO, PRESIDENT.

FIRST DAY—MONDAY, OCTOBER 20.

THE meeting of the Council and Fellows, the governing body of the association, was held in the hall of the New York Academy of Medicine, It was called to order at 2 P.M., by the President, Dr. Alvin A. Hubbell of Buffalo, who made a few remarks concerning the work done by the association during the past year. The membership of the association is now about 1,400, and five new county associations have been organized, viz., Albany, Columbia, Otsego, Steuben, and Rockland.

The Two State Medical Organizations.—The report of the work done by the joint committee of conference, appointed at the request of the Medical Society of the State of New York last winter, was presented by Dr. E. Eliot Harris. At the first joint conference, held last March, the committee of the State association proposed that a new charter be applied for, and that the two organizations unite under the name of "The New York State Medical Society," and that all members in good standing in both bodies be made charter members. This was done because the organization of the State society was found to be intricate and unwieldy. At the request of the State society, it was agreed that the united bodies should take the present name of the State society, but have practically the organization of the State association. It was also agreed that the reconstituted medical body should be the representative in this State of the American Medical Association by virtue of the constitution and by-laws adopted in 1901. At the last conference the State society committee took the stand that they could not recommend the acceptance by the State society of the by-laws of the American Medical Association, containing as they did, the code of medical ethics. The joint conference adjourned *sine die.* On motion of Dr. E. D. Ferguson of Troy, the following resolutions were unanimously adopted:

Resolved, That the report of the committee appointed to confer with a committee representing the Medical Society of the State of New York for the purpose of devising a plan for the union of The New York State Medical Association and the Medical Society of the State of New York is hereby approved;

Resolved, That the plan presented at the joint sessions of the two committees by the committee representing this association, whereby 'The New York State Medical Association and the Medical Society of the State of New York be reconstituted by an act of the Legislature into a State medical body, to be known as the Medical Society of the State of New York, of which all members in good standing in both bodies shall be charter members, and the reconstituted State medical body shall be the representative in this State of the American Medical Association by virtue of its acceptance of the constitution and by-laws of the American Medical Association," is hereby accepted by The New York State Medical Association as an expression of our sincere desire for a union of the medical profession in this State.

Resolved, That the committee is hereby continued for the purpose of co-operating with any committee from the Medical Society of the State of New York to secure a charter from the Legislature at its next session in 1903, which charter shall reconstitute the two State organizations into one State body as set forth in the preceding resolution; but if the Medical Society of the State of New York shall fail to approve of such plan of union by a charter to be secured at the approaching session of the Legislature in 1903, then this Committee shall be considered as discharged and the proposition of this Association withdrawn.

Resolved, In case this committee should find occasion to apply to the Legislature at its next session for the purpose of securing the said charter it shall co-operate with the standing commitee on legislation of this association.

Fees Changed.—The initiation fee of five dollars was abolished, and the annual dues were changed from five to six dollars, a rebate of one dollar being allowed if payment were made within the first three months of the year. The fine for delinquents was abolished.

Medical Defense of Members.—Among other changes made in the by-laws, was the important one which imposes on the council the duty of defending, in their discretion, the members of the New York State Medical Association in suits for alleged malpractice. The plan of associated defense is that which has already been put into operation by the New York County Medical Association, and is briefly as follows: "(1) The council shall, upon request and compliance with the conditions hereinafter provided, assume the defense of suits for alleged malpractice brought against members of this association. (2) The council shall not undertake the defense of any suit based upon acts prior to the qualification of the accused as a member of the association. (3) A member desiring to avail himself of the provisions of this article shall make application to the council through the secretary, shall sign a contract renouncing his own and vesting in the council sole authority to conduct the defense of said suit or to settle by compromise, and shall make such other agreements as the council may require. (4) The council shall thereupon contract with said applicant to take full charge of said suit, to furnish all necessary legal services, to pay all necessary expenses, and not to compromise said suit without consent of the accused, but the council shall not obligate the association to the payment of any damages awarded by decree of court or upon compromise."

Officers Elected.—*President:*, Dr. Frederick Holme Wiggin of New York; *Vice-President*, Dr. William H. Thornton of Buffalo; *Secretary*, Dr. Guy D. Lombard of New York; *Treasurer*, Dr. E. H. Squibb of Brooklyn; *Chairman of Committee of Arrangements*, Dr. S. A. Brown of New York; *Chairman of Committee on Library*, Dr. John Shrady of New York; *Chairman of Committee on Legislation*, Dr. E. Eliot Harris of New York; *Chairman of Committee on Public Health*, Dr. J. Scott Wood of Brooklyn; *Chairman of Committee on Publication*, Dr. Emil Mayer of New York; *Chairman of Committee on Nominations*, Dr. Charles E. Quimby of New York.

SECOND DAY—TUESDAY, OCTOBER 21.

The Pathogenesis of Eclampsia.—Dr. FREDERICK P. HAMMOND of New York presented this paper. He said that the degree of toxicity of the blood formed a fair criterion on which to base a prognosis in the individual cases of eclampsia. The underlying principle of treatment should be a judicious prophylaxis. Every case of headache should receive attention, and the patients should be taught the necessity of medical supervision throughout pregnancy. If the specific gravity of urine were 1012 or less, even though nothing else were discovered on analysis, the physician should at once prescribe some remedy which would increase the urinary solids. The best for this purpose was the tincture of the chloride of iron, ten minims three times a day, given in lemon juice. For the headaches, the bromides would be found the best, and the coal-tar products should only be given with great caution in pregnancy. Disturbance of vision and the occurrence of vertigo were often the result of disturbance of the liver or alimentary canal, and such cathartics as podophyllin and elaterium were indicated. If the urine were of a moderately deep color, diminished in quantity and having a specific gravity of 1012, the condition was a dangerous one. If with these there was albuminuria, the prognosis was decidedly bad. Albumin was often absent from the urine prior to an eclamptic seizure, but it was almost always present, coincident with or immediately after, the eclamptic attack. The best prophylactic treatment was the selection of a diet which would minimize the accumulation of toxins in the system. The diet should contain fluids in abundance. Wheat bread, from its richness in nucleoalbumins, should enter into the diet at every meal. The morning meal should consist of an abundance of fresh fruit, always peeled, and the fluids should be weak tea, coffee, or water. There should be no meat. The mid-day meal should be the chief one of the day, and only at this meal should the red meats be permitted. Red meat wasa special nerve excitant. The evening meal should be light, and should be of greater bulk than the morning meal. When headache, disturbance of vision, vertigo, or epigastric pain occurred, the patient should be at once put upon a fluid diet, consisting for the most part of milk, but including shell-fish broths. Under no circumstances should the meat extracts be allowed. When the colon or lower bowel were at fault the cascara compounds were especially useful. If there were persistent flatus, the common rhubarb and soda mixture would often act most happily. A sluggish liver was chiefly at fault in connection with the accumulation of toxins in the system. Under such conditions podophyllin and elaterium were particularly indicated. Cold bathing should be interdicted throughout the entire period of uterogestation, though warm baths should be taken regularly twice a week. When the symptoms pointed to danger there should be no delay. The cervix should be dilated with the finger and the patient given a good dose of croton oil. To avert the attack, when imminent, the speaker said he knew of nothing better than chloral hydrate, though admitting its dangers. The paralyzing effect of veratrum viride seemed to him to be so great as to interfere with the progress of labor.

Bacterial Flora of the Vaginal and Cervical Canal in Health, with Remarks Concerning Infections of the Female Genital Tract.—Dr. William E. Swan of Saratoga Springs presented this paper. He said that our knowledge of the bacteria of the vaginal secretions was of comparatively recent date, the first effective study having been that of Döderlein in 1892. He did not find any pathogenic germ in the normal vaginal secretions, except the thrush fungus, which, only to a limited extent, was capable of producing suppuration and destruction of tissue when injected under the skin or into the eye. This observer attributed the germicidal action of the normal vaginal secretion to the product of acid environment or to the vaginal bacilli. In only eight out of 195 cases examined were streptococci found, and in only five of these was it possible to determine by inoculation experiments that the streptococci were virulent. Krōnig, in about 200 examinations, found that the vagina of the pregnant women, aside from the gonococcus and the thrush fungus, there were no pathogenic microorganisms. He attributed the germicidal properties of the vagina to the outward flow of the vaginal secretions, and not to any special microbe having its normal habitat in the vagina. Walthard found in the vaginal discharges, both during pregnancy and after delivery, streptococci, staphylococci, gonococci, and colon bacilli. The vaginal streptococci were not found to be virulent, and acted as saprophytes on healthy tissues, and only became infectious when the resistance of the tissues were diminished. According to Miller, the gonococcus was by far the most frequent invader of the uterine cavity. Dr. J. Whitridge Williams of Baltimore, in forty examinations of pverperal cases, found streptococci in eight, staphylococci in three, colon bacilli in six, gonococci in two, anærobic bacilli in four, diphtheria bacilli, gas bacilli, and typhoid bacilli each in one case. If a healthy vagina became infected by active virulent organisms it would rid itself of these in from six to thirty hours, while if attempts were made by antiseptic douches to assist nature this self-cleansing process would require from twenty hours to three days.

Treatment in Gynecology from a Medical Standpoint.—Dr. Mary Gage-Day of Kingston was the author of this paper. She said that there was no historical ground for the belief that the diseases of women were practically unknown among the ancients. When women came to her with cancer, tumors of any kind, pus collections, or injuries due to childbirth, she explained to them that surgical treatment was demanded. The balance of gynecological cases, consisting of inflammations and displacements, were amenable to medical treatment alone. In the local treatment of women prior to the menopause, if restricted to a few remedies, she would select four drugs, viz., iodine, ichthyol, glycerin, and boric acid. For the treatment of that condition, known clinically as endometritis, she made use of a mixture of iodine, one drachm, boric acid, two drachms, and glycerin, four ounces. When there was much tenderness about the uterus she preferred to use ichthyol. In many cases curettage should precede medical treatment. Two cases of hemorrhagic metritis were reported, in which, after prolonged local and medicinal treatment without avail, adrenalin chloride, given internally in doses of five to ten drops, four times a day, gave great relief, and did not distqrb the stomach. It was her experience that women past the menopause do not bear so well treatment with iodine, ichthyol, and glycerin. In such cases she had had better results from the use of the following mixtures: Irish moss, half an ounce; glycerin, two drachms; alcohol, four ounces; boric acid, two ounces; water sufficient to make one quart. Its preparation was troublesome, but when properly done the mixutre is bland and mucilaginous, of about the consistence of glycerin and having great healing properties. The points specially emphasized were: (1) The physician should be clean in his own person, instruments, and work; (2) He should thoroughly examine the patients; (3) He should carefully instruct his gynecological patients regarding the hygiene of daily life; (4) He should use simple but appropriate remedies, and (5) He should conduct all local treatment with both skill and gentleness.

Dr. J. H. Burtenshaw of New York City complimented the author on this most practical paper. He thought the failure to appreciate the full value of hot vaginal douches was most unfortunate.

Dr. J. Riddle Goffe of New York City said that while he had not given adrenalin internally, he had made use of it frequently as a local styptic in plastic operations. When there was a large raw surface left in the vagina during the operation of anterior colpotomy, or in the course of denudations in operations upon the lacerations of the cervix and perineum, a few drops of adrenalin solution swept over the bleeding surface would give a clean field for operation.

Dr. Richard H. Gibbons of Scranton, Pa., said that the originator of the hot-water treatment had advised the use of the Davidson, and not the fountain, syringe, believing that the impact of the water was an important factor in the treatment. Dr. Emmett used to be able to state, from examination, which patients in the Woman's Hospital had received douches with the Davidson and which with the fountain syringe.

What Advice Should Be Given to a Woman Suffering from Fibroid Tumor of the Uterus.—Dr. J. Riddle Goffe of New York read this paper. It was admitted, he said, that fibroid tumors occasionally cease to grow and remain sationary, perhaps, for years, or even disappear. However, such a favorable termination was exceedingly rare and should be looked upon as a medical curiosity. Posalpinx and ovarian abscess were the chief complications of fibroid, although the etiology of pus formation in connection with these growths was not very clear.

Metrorrhagia was often very severe, and postponed the menopause for many years. In an exceedingly small proportion of cases treated by electricity had the tumor disappeared, and in these it was not improbable that this disappearance was really spontaneous and coincidental. Moreover, a large experience condemned electricity as a harmful agent. Curettage was occasionally successful, but, as a rule, it required frequent repetition, and often, ultimately, became a dangerous procedure. The author was of the opinion that the proper treatment of fibroid tumors was immediate removal by operation, whether the tumor was large or small, and in both single and married women, except the patient was advanced in years, or pregnancy was a complicating condition. In the majority of cases of fibroids, complicated by pregnancy, there was a normal delivery at full term. Cæsarean section at full term was safer for both mother and child than myomectomy during gestation in the rare instances in which such operation was required.

The Principles Involved in the Repair of Lacerations of the Pelvic Floor.—Dr. James Hawley Burtenshaw of New York City presented this paper. He said that while it was formerly taught that on the integrity of the so-called perineal body depended the maintenance of the normal positions of the organs of the pelvis, it was now generally conceded that its function was solely to give needed support to the curve of the rectum during the expression of intra-abdominal force. Rupture of this body might occur even through the anal sphincter, yet pelvic equilibrium would not be disturbed if the muscles composing the pelvic floor remained intact. By means of drawings, the speaker described the attachments of the levator ani muscle and its fascia, laying particular stress on the important rôle of the latter in imparting strength to the pelvic floor and preventins prolapse. He questioned if the majority of modern operations of perineorrhaphy and colpoperineorrhaphy actually restored the pelvic floor to its normal condition. As the denudation extended only through the mucous membrane of the vaginal wall, the muscles were only backed up against themselves, and in this position they served to reduce the lumen of the canal, partially close the orifice, and restore the curves of the vagina and rectum. While admitting that an operation of this kind apparently fulfilled all indications, he claimed that here, as elsewhere in the body, if a muscular rent was to be closed the edges of the muscle must be freshened and closely approximated by sutures. Many operators had appreciated this defect in plastic surgery of the posterior wall and had evolved special methods for the suture of these superficially denuded areas, but in each case the object had not been attained because the underlying muscles were not directly approximated. Emmet was the pioneer in correctly attributing to the pelvic floor its proper function, but the operation known by his name did not, the speaker thought, accomplish all that its author claimed for it, because the levator and its fasciæ were bound to retract as soon as the retaining sutures were removed. The author's conclusions were: (1) The rôle of the pelvic floor in sustaining the pelvic viscera being acknowledged, a laceration of the muscles and fascia composing the most important section of this floor should be repaired, in order to restore the natural equilibrium of the pelvis; (2) While a majority of the plastic operations on the vaginal wall restore the natural curves of the vagina and rectum, and reduce the size of the vaginal outlet, to restore the pelvic floor to a normal condition approximation and suturing of the edges of the levator-ani muscle and its fascia is imperative.

Dr. E. D. Ferguson of Troy said that in every operation done by through-and-through suturing on tightening the sutures they were thrown into a circle, and consequently the retracted tissues were not brought together, particularly in the center. They were only united by scar-tissue, and such tissue would always yield. He had not always found it possible to recognize the different layers of retracted muscle and fibrous tissue. If the pelvic fasciæ were brought together with any kind of suturing, the fibrous and muscular tissue would be brought together, and there would, probably, be good union.

Dr. Frederick Holme Wiggin of New York City said that the important thing was to bring together these separated muscles and hold the rectum in place. He had been in the habit of making an incision at the junction of the mucous lining of the vagina and the skin, lifting the flap, according to the method of Tait, up to the highest point of the rectocele, and then incising on either side, so as to raise this flap. Having raised the flap, it would be found that the rectum could be pushed back into place, and that the outline of the muscles could be felt. The parts were then coaptated with buried sutures of catgut or kangaroo tendon.

Dr. R. H. Gibbons of Scranton, Pa., said that if there were merely a laceration of the fascia nothing more was necessary than to expose the fascia and dissect out the cicatricial tissue or cut away the overstretched fascia. The operation of Emmet, if properly done, with complete denudation—not merely snipping off the mucous membrane—brought the parts to their original position.

Dr. Eden V. Delphey of New York City said that by the insertion of the finger into the vagina laterally one should determine whether there was resistance toward the ischium, for, if not, the laceration was quite extensive. The effect of the tear in the levator ani was to cause retraction of the posterior fibers of the muscle, and greatly to impair the support of the pelvic organs.

Dr. David P. Austin of New York City thought that better than all the operations thus far mentioned was immediate perineorrhaphy, even in cases in which the laceration extended well into the rectum.

Dr. Theodore P. Simpson of Beaver Falls, Pa., said that in all cases there were a rectocele and a vaginocele, and that in order to restore the parts to their normal shape as well as condition the extension, so to speak, of the floor of the vagina must be removed—in other words, the redundant part of the mucous membrane must be reduced. In Kelly's operation, the muscular fibers were brought together quite perfectly, being attached not only from side to side, but, to some extent, also from end to end. In this way the natural curvature of the vagina was replaced.

Dr. J. Riddle Goffe of New York City said that the old operation was very defective, in that it dragged the tissues downward. His own plan was to bring together the parts by a single line of sutures from the highest point of the rectocele above to the caruncles on the sides.

Symposium on Colds.—This was the special order for the opening of the afternoon program.

Etiology of Colds.—Dr. James J. Walsh of New York City opened the discussion with this paper. He cited instances to emphasize the statement that cold was only a predisposing factor, the chief etiological element being a microbic invasion. At the beginning of an ordinary cold in the head the serous flow was an effort of nature to relieve the congestion and eliminate the infection; hence it should not be interfered with at this stage. The dry air of artificially-heated houses in winter was one cause of nasal irritation. Not infrequently pharyngitis and tonsillitis would follow mouth-breathing, necessitated by running or by some unusual demand upon the upper air passages. Many attacks of tonsillitis, bronchitis, and pneumonia followed going to some crowded place, and then passing immediately into the cold air outside. The congestion thus produced favored an infection by the numerous microbes which had lodged in the upper air passages while the person was in the heated and crowded room. This suggested the wisdom of tarrying a short time in the corridors of places of amusement before going out into the cold air. It was obvious also that greater attention to the hygiene of these public places, including sanitary dusting and cleaning, should constitute one factor in prophylaxis. The fever which acompanied a cold pointed very strongly to the infectious nature of this familiar affection. A distinct incubation period could ordinarily be traced, and the origin of the cold was frequently much farther off than was supposed.

Symptomatology of Colds.—Dr. George F. Cott of Buffalo read this paper. He said that a cold was a disease entity in the minds of the laity, but with the physician it always meant a condition secondary to something else. A person with nasal polypi, for example, would complain of almost constant stuffiness of the nose; one with an enlarged lingual tonsil became hoarse after very slight use of the singing voice. The familiar symptoms were then detailed.

The Treatment of Colds.—Dr. A. Alexander Smith of New York City discussed in this paper the treatment of colds involving the portions of the air passages situated above the vocal cords. He said that he was a believer in the view that some colds in the head are communicable, and that in some instances isolation might be a useful protective measure. In those prone to contracting colds some protection was afforded by the almost constant use of cod liver oil. The early and prompt treatment of some underlying diathesis, such as lithæmia, would often check the full development of a cold. The first thing he did when asked to prescribe for a cold was to ascertain if there was any elevation of the body temperature, and if this were 100°F. or over he insisted upon the patient's remaining home, and better still, in bed. In this way his comfort was promoted and in the end time was saved. A moderate dose of quinine and Dover's powder at night, followed in the morning by a cathartic, would certainly cut short some colds. Often no further treatment would be necessary than the administration of two grains of quinine, three times a day. The old domestic treatment by a hot mustard foot bath at bed-time should not be despised as means of promoting the patient's comfort. His own experience with the well-known "rhinitis tablets" was that if taken sufficiently early they would often "break up" a cold. In many patients susceptible to belladonna these tablets would give rise to the unpleasant physiological effect of that drug, yet it was necessary to push it almost to this point in order to secure the proper effect from these tablets. Another method of treatment, which was exceedingly satisfactory, was the alkaline treatment. This consisted in giving one drachm of bicarbonate of sodium in half a glass of water, and adding as a flavoring, a very few drops of lemon juice. This dose should be repeated in one hour. This treatment was often disappointing, however, in those who were not lithæmic. Sodium salicylate could be given in a dose of ten grains, repeated in an hour, and then in doses of five grains, at intervals of five or six hours, provided always it did not cause disturbance of the stomach. Camphor internally and by inhalation often yielded good results in the treatment of colds. A combination of phenacetin or antifebrin in small doses with quinine frequently proved beneficial in persons suffering from cold and having a dry, hot skin associated with muscular pains and headache. The great objection to it was that while it seemed to reduce the severity of the cold it would do so only to a certain point, and almost invariably prolonged the affection. In cases of moderate severity attended by an excess of mucopurulent secretion he had found great benefit from the use of creosote or of guaiacol carbonate in small doses. Thus, he would give one minim of creosote, or an equivalent of guaiacol every hour for the first day, and then continue it at longer intervals. The taste of creosote was objectionable, but there were certain pharmaceutical preparations by means of which it was disguised. They should be given every hour for six days and then every second hour, according to the indications. Carbolic acid had had many advocates, but he had been unable to satisfy himself that it was useful in ordinary acute catarrhal colds unless these were associated with great gastro-intestinal disturbance. For children under twelve years of age it was well to give very small doses of the tincture of aconite, repeated at intervals of an hour. The Turkish bath was rarely useful, except at the very beginning, and then should be used in connection with the administration of quinine, alkalies, or the vegetable bitters. Turpentine, terebene, and terpin hydrate had not proved useful in his hands in ordinary colds, except those involving the air passages below the vocal cords. He was not a great believer in the local treatment of colds, though he would admit that irrigation with saline solution was often useful. It was, however, dangerous, except in skilled hands. When there was a tendency to the recurrence of colds, benefit would sometimes accrue from the administration of very large doses of the tincture of the chloride of iron, given for only two or three days. He would give twenty minims of this tincture well diluted at each dose. Another agent of the greatest service was cod-liver oil; it would often produce an absolute cure as well as prevent recurrences. For those who found difficulty in taking it, quinine might be substituted in small doses, or else the vegetable bitters given. Sometimes the tendency to recurrence could only be absolutely relieved by a change of climate.

Dr. W. H. Thornton of Buffalo insisted that if local applications were employed at all they should be non-irritating. A weak alkaline spray was one of the best local applications. It should be used gently for two or three minutes, and then followed by a very mild oily spray, such as five grains of camphor to the ounce of one of the oily bases commonly used. Many oily sprays contained too much eucalyptol and thymol, and while they opened up the nostrils very satisfactorily the reaction frequently left the patient in a worse condition than before. If the nostril were completely occluded a weak solution of adrenalin chloride would certainly give relief, and its effect could be prolonged by the subsequent use of an oily spray.

Dr. W. Freudenthal of New York City objected to the prevailing tendency of calling everything an infection. Infections of the air tract were undoubtedly quite frequent, but a common cold, in his opinion, was nothing else than the effect of the lowered temperature upon the human system. About ten years ago he had investigated the dryness of the air in dwelling-houses, and had found that often there was only 15 to 18 per cent. of humidity. A person living in such dry air would develop a catarrh, which would, perhaps, last all winter. It was not a true cold, but a chronic post-nasal or similar catarrh, which, at times, underwent exacerbation. To overcome the susceptibility to catching cold one should not only resort to cold bathing, but should carefully avoid over-dressing.

Dr. G. W. Murdock of Cold Spring said that no mention had been made of a remedy upon which he placed great reliance in the treatment of colds—gelsemium. One or two doses of 10 to 20 drops of the fluid extract of gelsemium, taken at night, with or without liquor ammoniæ acetatis, would go a long way toward breaking up a cold.

Dr. A. H. Brownell of Oneonta thought the best treatment was that which antedated the cold itself, and which was directed towards the removal of such pathological conditions as enlarged tonsils and turbinates.

Dr. Cott said that almost all colds in children were due to obstruction in the nasopharynx and the removal of this would remove the tendency to colds. When a cold affected the trachea it gave rise to one of the most harassing coughs imaginable, but could be almost always relieved by an intertracheal injection of oil containing 5 per cent. of menthol.

The Newer Relation of the Pancreas to General Medicine.—Dr. Alfred Stengel of Philadelphia presented this paper. He said it had been satisfactorily demonstrated by the results of partial extirpation of the pancreas, that the results of complete extirpation of this organ were dependent upon the removal of its glandular activity, and were not due to shock. The pancreas probably secretes something which is concerned in the formation of sugar. The evidence in our possession suggests a close relation between diabetes and lesions of the islands of Langerhans, but it could not be asserted that the pancreas always played a part in the development of diabetes. No reliance could be placed upon indicanuria in determining the presence or absence of disease of the pancreas. The determination of the presence of fat-splitting ferments in the urine might, in time, become a means of diagnosticating disease of the pancreas. No reliance should be placed upon fatty diarrhœa as an indication of pancreatic disease. Deep-seated and intense epigastric pain of sudden onset, associated with collapse, was fairly characteristic of acute pancreatitis. Glycosuria, it should be noted, was by no means a constant symptom of pancreatic disease, even when the latter was of considerable extent.

A Preliminary Study of the Metabolism in Myxœdema Before and After the Administration of Thyroid Extract.—Dr. C. N. B. CAMAC and Dr. HASTINGS of New York City presented this paper, which was read by Dr. Camac. The subject of this study was a married woman of fifty-two years. On May 28 the use of thyroid extract was begun, and when the most marked fall in body weight occurred she was receiving thirteen grains of this extract daily. A loss of over twenty pounds was noted in two months, but in this preliminary communication they were not yet able to say, despite the elaborate research that had been made, just where this loss occurred.

Dr. ALFRED STENGEL said that the lack of rapid proteid consumption in this case was most interesting. The work of other experimenters regarding the action of thyroid extract in other conditions than myxœdema seemed to show that this remedy was capable of causing a rapid destruction of proteids in these other conditions. The different effect of the thyroid extract in myxœdema was not surprising when one remembered that this remedy exerted a specific action in myxœdema.

Dr. WOLFF said that it was very remarkable that, with the rapid loss of weight, the intake of nitrogen was greater than during the period of thyroid administration. This apparently showed that the loss was not due to proteid destruction, but either to the elimination of water or, perhaps, of fat.

Dr. J. J. WALSH expressed the opinion that the milder grades of myxœdema were not uncommon, though often overlooked in diagnosis. Many young people, about the time of puberty, became unnaturally stout, owing to a failure of the thyroid gland to develop properly.

The Present Position of Gallstone Surgery.—Dr. WILLIAM WOTKYNS SEYMOUR of Troy was the author of this paper. He pointed out that many deaths resulted from the prevalence, even at the present day, of the belief that gallstones can be dissolved by internal medicine. Again, contrary to general opinion, jaundice was not a very prominent symptom of gallstones, and when it was deep, and persisted, it suggested malignancy rather than gallstones. At the present time, in uncomplicated cases of gallstone surgery, one could promise an almost certain cure. However, when procrastination had converted an otherwise simple case into a complicated one, the mortality might rise to 40 per cent. Of forty-four gallstone operations that he had done, only six had proved fatal. The fatal cases were reported in detail.

A Study of the Indications of Nephropexy.—Dr. AUGUSTIN H. GOELET of New York City read this paper. The author insisted that the operation was indicated when there was prolapse of the kidney of the third degree, or beyond, *i. e.* when the organ was entirely below the border of the last rib in front. The indications for the operation were dependent upon: (1) The symptoms produced by the displacement of the organ; (2) The influence it exerted in producing or maintaining pelvic diseases in women, and (3) The influence exerted in causing disease of the kidney itself.

Dr. A. ERNEST GALLANT of New York City declared that even after the fixation of the kidney by operation the symptoms still persisted in 95 per cent. of the reported cases, and that a cure was not secured after such operations unless great attention were given subsequently to the support of the abdomen. For years it had been his practice to treat these cases by the proper application of a corset similar to the straight-front corset now in vogue. When the kidney was held in position by such means it could not be forced down by the patient if the corset were properly applied. His plan was to place the patient on a couch and take the measurements for the corset in that position. The corset was applied with the patient lying down on the couch with the hips raised. She was instructed while in this position to lace the lower part of the corset as firmly as possible, but to keep the upper portion very loose.

Dr. PARKER SYMS of New York City said that in some cases of prolapsed kidney, associated with neurasthenia, there was room for a difference of opinion as to the best course to pursue. In some of them operation would do harm rather than good; in other cases the neurotic condition was the result of the floating kidney, and in the latter, if the operation were done sufficiently early, the result should be good. If the woman were feeble and nervous he preferred to improve her general condition before operating. He had had no personal experience with mechanical supports, but the results reported from such treatment had not been satisfactory.

Dr. MAX EINHORN of New York City said he had seen a very large number of cases of displaced kidney, and had made it a point to examine the urine carefully, with the result that he had very seldom found disease of the kidney as such. Some of these patients had been kept under observation for a number of years, and had presented no evidence of renal disease at any time. There was associated with most cases of movable kidney a condition of general enteroptosis. In almost 95 per cent. of these there was a gastroptosis, and in many the colon was also prolapsed. It was obvious that restoration of the kidney to its proper place would not favorably affect the other displacements—indeed, he thought it actually favored the descent of the other organs by increasing the capacity of the abdomen. The indication was to make the abdomen smaller, and this was best accomplished by improving the general nutrition and by bandaging. Even if the kidney were moveable to the fourth degree, and remained in this position, it did not ordinarily give rise to any special disturbance, provided the patient was otherwise healthy. He had not yet met with any cases of movable kidney which, in his estimation, required operation, and his results had been very satisfactory. The literature, he believed, showed that there was a mortality of 2 per cent. associated with the operation of nephropexy, and this was too large to be lightly disregarded.

Dr. GIBBONS expressed the opinion that the kidney should be promptly fixed by operation to prevent certain disastrous results, such as Bright's disease, stone in the kidney, and malignant disease. About fifty years ago the renowned surgeon John Carnochan of New York City devised what is now known as the French corset for the purpose of relieving the symptoms of gastroptosis. This was the corset recommended by Dr. Gallant.

Dr. GOELET, in closing the discussion, replied to the criticism regarding the mortality of nephropexy by saying that this operation was still in its infancy. He had himself done 139 nephropexies on 112 patients, and had not lost a single one. On this experience he based the statement that there was no mortality to this operation. He did not think general enteroptosis was associated with prolapse of the kidney in more than 25 per cent. of the cases. He recalled but two cases in which the symptoms had not been relieved very shortly after the operation, and in one of these they had disappeared after about six months. The other case had only been operated upon a week or two ago. In not a single instance in which he had

had made a careful microscopical examination of the urine in cases of prolapse of the kidney to the third degree, or over, had there been absence of renal disease. He believed that nephroptosis was the most important element, even in cases of general enteroptosis. The kidney should be fixed by operation, and the other organs held in place by mechanical supports.

The Surgical Diseases of the Kidneys from the Standpoint of a General Country Physician.—Dr. George A. Leitner of Piermont presented in this paper a report of three interesting cases, and also exhibited the pathological specimens. The cases were respectively, stone in the kidney, abscess of the kidney, and adenocarcinoma of that organ.

A Case of Leprosy.—Dr. William S. Gottheil of New York City exhibited a very well marked case of leprosy of the face and hands of long standing.

The Relation of Obesity to Improcreance.—Dr. Heinrich Stern of New York City presented this paper. He said that the apparent relation of improcreance and polysarcia had been often noted. He had treated for polysarcia forty-eight women, thirty-four of whom were married. One had never menstruated; twelve had never been pregnant; in eight single or double oophorectomy had been performed; five had always had scanty and irregular menstruation; in two the catamenia had prematurely ceased; four had various congestive or inflammatory conditions of the sexual organs, while only six seemed to have been entirely free from ovarian and uterine derangements. Of 100 women at the menopause, chosen by him at random, eight were not certain whether they had gained or lost; twenty thought they had retained their previous bulk; twenty-nine had lost weight and circumference, and forty-three had developed more or less marked polysarcia. Experienced breeders did not always depend upon castration alone to procure profitable live stock, but had recourse to three valuable expedients, viz.: (1) Over-alimentation; (2) compulsory rest, and (3) lack of sunlight. It was interesting to note that many hibernating animals lose but little weight while in their dark hiding places. The non-performance of sexual functions by preventing expenditure of certain body material might facilitate the fattening process. It was not improbable that the reduction of protoplasmic catabolism might constitute the basis of obesity in the improcreant. All the possible factors underlying the association of improcreance and obesity were found to depend upon diminished intraorganic oxidation.

A Case of Idiopathic Brain Abscess with Focal Symptoms Diagnosed as Brain Tumor.—Dr. Herman G. Gordinier of Troy reported this interesting case. The tumor was in the motor area just beneath the cortex. The author's conclusions from a study of this case were: (1) It showed the necessity for exploratory puncture or incision in every apparently inoperable case of brain disease, regardless of the supposed pathological lesion; (2) This case confirmed an opinion expressed by him in a previously published article, *i. e.* that typical attacks of Jacksonian epilepsy might be excited quite as well by a lesion just below the cortex as by one upon it; (3) That the case showed no disturbance of sensation other than those in the arm; and (4) That the case confirmed the value of local convulsive movements as a means of locating brain disease.

A Case of Melancholia Agitans.—Dr. William E. Douglas of Middletown presented this clinical report.

Report and Presentation of a Case of Idiopathic Atrophy of the Skin.—Dr. R. Abrahams made the clinical presentation, and Dr. William S. Gottheil described the results of microscopical examination. Dr. Abrahams said that not more than twenty such cases had been reported. The important features were the slow progress of the pathological process and the absolute failure of all remedial agents to arrest the disease. The microscopical examination revealed a general atrophy of all the elements of the skin following upon, and the result of, chronic inflammation.

Unrecognized Toxic Insanities.—Dr. T. D. Crothers of Hartford, Conn., was the author of this paper. He asserted that the toxic insanities, particularly from spirits and drugs, are increasing. The strange conduct of persons high in active life, together with strange and unexpected crimes, were found to be largely associated with spirit and drug taking, indeed were practically due to this one cause. A closer study showed a distinct origin, progress, and development of a psychosis, with progressive degeneration of the brain and nerve centers. The paralyzing anæsthetic action of alcohol, first on the sensory and then on the higher centers, was very apparent in these cases. A large percentage of the insanities occurring in the higher circles were both directly and indirectly due to the use of drugs and spirits. These causes were largely unrecognized except in the latter stages. Changes of conduct, character, habits, and manners of persons who use spirits and drugs could only be explained as true psychoses. It was said, on the very best authority, that fully one-fourth of the medical practice in this country among the better classes of society was directed to the correction of injuries following from the abuse of alcohol and drugs.

THIRD DAY—WEDNESDAY, OCTOBER 22.

Strangulated Hernia in Children Under One Year of Age. Dr. W. B. Reed of Rome, N. Y., in this paper presented a report of a successful herniotomy done by him on a male infant, twenty-seven days old. The tumor, which was the size of a hen's egg, was situated in the right inguinal region. The tumor was very tender, and there was no impulse on crying. The child was inverted and taxis tried, but without success. At the operation, the point of strangulation was found to be at the internal ring, and was so very tight that two incisions into the constricting band were required in order to liberate the hernia. Dr. Reed said that although congenital hernia was quite common in children, the occurrence of strangulation in a child under one year old was extremely rare. He had been able to find only nine such cases, including his own. The rarity of strangulation in children was probably due in large part to the softness of the involved structures. He thought the mortality should be considerably less than 10 per cent. in infants under one year of age. if the operation were promptly done, even by a surgeon of moderate experience.

Dr. A. J. Ochsner of Chicago was invited to open the discussion. He thought his own experience included fully as many cases as the entire number reported in the paper, but, like many other surgeons, he had not reported specially upon them. As a matter of fact, children bore herniotomy remarkably well. About 97 per cent. of the cases of non-strangulated hernia were cured spontaneously. The operation in strangulated cases was very simple.

Local Anæsthesia in Radical Cure for Inguinal Hernia.—Dr. J. A. Bodine of New York City was the author of this paper. It was based on forty-eight cases of inguinal hernia operated on under local cocaine anæsthesia. In no case was more than one-half a grain of the muriate of cocaine used. The operator should endeavor to recognize and specially cocainize the three main nerve trunks to the part. The iliohypogastric nerve was the easiest to find, and if it were well cocainized the anæsthesia would be fairly satisfactory. The needle should be introduced just beneath the scarf epithelium of the integument—in other words, the injection should be introdermic and not hypodermic, and the anæsthesia could be painlessly deepened down to the aponeurosis of the external oblique. The method of introduction should be such as to produce œdematization and acute anæmia of the skin. A one-per-cent. solution of cocaine would anæthetize the skin for an hour and a half. In the forty-eight cases referred to, all three nerve trunks had been identified seventeen times, and the iliohypogastric nerve in every case. Whenever a blood vessel was cut or tied it caused acute pain. He had found that cocaine solutions could be boiled for a minute or two without causing any deterioration in them.

Dr. **John A. Wyeth** of New York City said that in his own experience probably 50 per cent. of hernia patients who refused operation did so because of their fear of narcosis. With the weaker solutions of cocaine one must use a wider circle of infiltration, and this was important because one of the objections to the infitration method was the traumatism which the cocaine inflicted upon the tissues. The injection of the cocaine directly under the integument was essential, and with these weak solutions there could be no danger of cocaine toxæmia. By injecting two or three drops and then incising, the anæstheria was almost instantaneous, and the excess of the cocaine solution was allowed to escape. In his opinion, cocaine anæsthesia should not be used in difficult hernia cases. It was important that the cocaine solution should be sterile and that it be made freshly for each case.

Dr. **Lyle** said that his experience in the use of cocaine in herniotomy had not been so extensive as that of Dr. Bodine, but he had done thirteen of these operations under cocaine anæsthesia. His plan was to inject ½ per cent. solution into the skin, and he did not fear cocaine poisoning because morphine is a perfect physiological antidote. Of his thirteen cases the three nerves were found in seven. He thought it was important to use the cocaine solution hot, for in this way much less would be needed.

Dr. **A. Ernest Gallant** of New York City said that if one grain of boric acid were added to four ounces of a solution of cocaine the solution could be perfectly preserved not only for months but for years.

A Case of Large Cavernous Angioma of the Back.—Dr. **J. A. Wyeth** of New York presented a little girl with this condition, not only because of the intrinsic interest of the case, but because it showed the good results obtainable from Dr. Wyeth's method of injecting boiling water. He had employed this method in about half a dozen cases with encouraging results.

Intestinal Obstruction.—Dr. **John B. Harvie** of Troy read this paper, reporting many interesting cases, and presenting a number of pathological specimens. The histories presented demonstrated, in his opinion, the practicability of securing an almost positively favorable outcome from early operation.

Radical Operations for the Cure of Cancer of the Stomach. Dr. **William J. Mayo** of Rochester, Minn., presented this report. He said that Dr. W. G. McDonald had found forty-three cases of fndoubted cure after extirpation of cancer of the stomach; Murphy had collected 189 cases operated upon radically, by many well-known surgeons, with twenty-six deaths. Of these, seventeen, or about 8 per cent., survived three years. This was reduced to 5 per cent. by recurrences after three years, but, as many of these cases were alive and apparently well less than three years, the law of averages might be expected to at least maintain the 8 per cent. or better in due time. One-third of all cases of carcinomatous disease was located in the stomach. Gastroenterostomy usually prolonged life about three months, and radical operation gave an increase of fourteen months over the unoperated. In 100 cases Mikulicz found the average duration of life after operation to be one year and one-third, and that the patient was usually comfortable until shortly before death. The speaker declared that the reason these results were not better was that the diagnosis was not made sufficiently early. The stomach was a favorable organ for operation, having a large blood supply from several sources. The tendency to lymphatic infection was probably less in cancer of the stomach than in similar conditions in the breast, uterus, or rectum. A suspicion of malignant disease should warrant demanding a surgical consultation just as much as appendicitis, or ectopic pregnancy. A small movable tumor in the pyloric region, with obstructive symptoms, was a favorable element. His own experience led him to believe that, with symptoms warranting an exploration, the lack of definite signs usually meant an extensive and hopeless involvement of the body of the stomach. One source of delay in seeking surgical treatment was the prolonged attempts to make a diagnosis by various tests of the stomach contents. While such efforts were in the right direction, he thought, at the present time, they only served to waste precious time. Early operation should give as favorable a showing as cancer of the breast or uterus. In his own experience, cancer of the pyloric region had been the only form of the disease which he had been able to diagnosticate sufficiently early to attempt radical relief. The diagnosis was assisted by distending the stomach with air, using a Davidson syringe for this purpose, instead of the dangerous method of generating carbonic-acid gas, by taking into the stomach bicarbonate of soda and tartaric acid. As a rule, extension to neighboring viscera contraindicated operation, and extensive adhesions would greatly complicate the operation and increase the primary mortality. Lymphatic involvement, unless localized to the vicinity of the growth, was a hopeless complication. Extension along the lesser curvature was less favorable than along the greater curvature. In St. Mary's Hospital, during the past ten years, 213 operations had been made upon the stomach, 126 for non-malignant disease, with a mortality of slightly less than 5 per cent.; 92 for malignant disease, with nine deaths, or 10 per cent. Over one-fourth of the latter group were explorations, but none of these proved fatal. The author's experience of twenty pylorectomies, with two deaths, showed, in a general way, the satisfactory character of such operations.

Surgery of the Stomach for the Relief of Non-malignant Pathological Conditions.—Dr. **A. J. Ochsner** of Chicago presented this paper. He said that all stomach surgery at the present time was directed toward the relief of gastric ulcer, or one of its various sequelæ. His own clinical experience comprised operations upon twenty-seven patients for the relief of non-malignant disease of the stomach. When a gastric ulcer had perforated into the free peritoneal cavity, all observers agreed that only an early operation could give a reasonable percentage of recoveries. In all cases operated upon more than twelve hours after the perforation the prognosis was exceedingly bad; yet even in early operations the prognosis must always be bad; hence, the importance of surgically treating these cases long before the occurrence of perforation. It was found that serious ulceration of the stomach occurred only in the presence of faulty drainage. As the stomach dilated, the shape of the organ was altered in such a way as to form a pouch, thus increasing the obstruction. In a large proportion of these cases there was a decided tendency to progress from bad to worse. Proper permanent drainage could be most safely applied by making an anastomosis between the lowest point in the stomach and the duodenum, at a distance of about 40 cm. from the point at which the duodenum issues through the mesentery of the transverse colon. The essential points were the selection of the lowest point in the stomach and the proper length of small intestine. It was not necessary to excise the ulcer unless it was located directly in the pylorus, or unless it was impossible, in a given case, to make a positive differential diagnosis between ulcer and carcinoma. When there was a reasonable doubt, the ulcer should be excised if in a position to make this possible.

New Apparatus for the Treatment of Œsophageal Stricture.—Dr. **Theodore Dunham** of New York described an ingenious method which he had devised, and demonstrated its application. By means of a feeding tube and some water, he showed that along with the water it was easy to swallow the thread and carry it down into the stomach.

President's Address: "Reflections on Some of the Purposes and Work of the New York State Medical Association."—Dr. **Alvin A. Hubbell** of Buffalo delivered this address, after referring to the objects of the association, and to the important part it had played in securing higher medical education, the speaker described in eloquent terms the tremendous moral power which the code of ethics of the American Medical Association had exerted upon the profession of this country. He declared that this code, which the association had ever defended most devotedly, did not in the least restrict or cripple any right action. Human experience showed that it was unsafe to trust everything to an "unwritten code. In closing, the speaker described the present plan of organization, and predicted for it a brilliant future.

Symposium on Typhoid Fever—Pathology and Bacteriology.—Dr. George Blumer of Albany presented this paper. He said that in 1885 Fraenkel had succeeded in isolating the typhoid bacillus from the blood in one out of six cases. It was four years later before it was discovered that the frequent failures to isolate the organism were due to a faulty technique. Since then there had been reported 154 cases, in ninety-eight of which, or nearly 63 per cent., the typhoid bacillus was isolated from the blood. It was found that large quantities of blood were required, and that this must be obtained in a strictly aseptic manner, and that the blood must be largely diluted in order to offset its germicidal action. A similar modification of technique resulted in the frequent isolation of the bacillus from the rose spots. As a rule, the bacilli did not appear in the urine until relatively late in the disease—the end of the second week—and their presence in the urine was chiefly of prophylactic significance. The percentage of cases showing bacilli in the urine was variously stated by different observers, but might be estimated at 29 per cent. When the bacilli occurred in the urine they were present in enormous numbers. This showed that it was just as important to disinfect the urine as the stools of a typhoid patient, and it should be particularly noted that the cases in which the bacilli were found in the urine rarely presented any symptoms directing attention to the genitourinary tract. The occurrence of the bacilli in the bile had been first observed in 1888. In some cases gall-bladder lesions seemed to take the place of the ordinary intestinal lesions. In most cases the typhoid bacilli probably reach the bile through the blood. In only a few cases, in which an autopsy had been made in the first four weeks of the disease, had no intestinal lesions been discovered.

The Serum Reaction in Typhoid Fever.—Dr. Thomas W. Hastings of New York presented this paper. Many statistics were quoted, and in the aggregate they showed about 95 per cent. of positive Widal reactions, for the most part with a dilution of one in fifty. Negative reactions occurred in from 4 to 6 per cent. The similarity of the reaction in adults and children was worthy of note.

Paratyphoid Fever.—Dr. Nathan E. Brill of New York City was the author of this paper. He said that on December 1, 1897, he had presented to the Society of Alumni of Bellevue Hospital a paper based on seventeen cases which he had observed of a disease which presented the clinical picture, in the main, of typhoid fever, but had not given the Widal reaction. At that time he had expressed the opinion that it was a specific and distinct disease, but his laboratory investigations had been chiefly negative. They had, however, led to the discovery of an unindentified bacillus, which was not thought to be the cause of the affection. In these cases the fever reached its maximum in five days. The apathy was much more pronounced than in typhoid. One of the earliest and most marked features was the extreme prostration. The diazo-reaction was not constantly present in the urine. The blood showed no leucocytosis. The average duration of the disease was a little over two weeks, and relapses were observed in about 10 per cent. of the cases. The speaker added that paracolon infections were now known not to be very rare, thirty-eight cases having been reported in the past year.

Arteritis and Arterial Thrombosis in Typhoid Fever. Dr W. S. Thayer of Baltimore spoke on this subject reporting in detail five cases He said there was a complex of symptoms occurring occasionally in typhoid fever more particularly in the latter part, to which the French had given the name of "arteritis." It was suggested that acute arteritis might be the cause of some of the peculiar cases of aphasia developing during the course of typhoid fever.

The Modern Treatment of Typhoid Fever.—Dr. W. Gilman Thompson of New York City discussed this topic. Regarding the antiseptic treatment he said that there was good reason to doubt the possibility of giving intestinal antiseptics in such potency as to result in the destruction of the typhoid bacilli in the bowel without at the same time injuring the patient. Moreover, recent knowledge pointed to such a wide distribution of the bacilli throughout the body that it weakened greatly the argument in favor of such antiseptic treatment. A recently published series of over 200 cases showed the presence of the typhoid bacillus in the blood in 87 5 per cent. of the cases. An initial dose of calomel was useful, but the daily administration of calomel throughout the course of the disease was more apt to effect the salivation than the salvation of the patient. Where, for any reason, milk diet was inadvisable, the patient should be nourished by giving broths, egg albumin mixture, peptonoids, or panopepton. Flatulent distention could be best relieved by the use of the rectal tube. Water should be given very freely. There could be no greater mistake than to treat all typhoid cases by one dietetic rule. The diet should be increased as soon as the temperature reached the normal; sometimes even when it hovered about 100°F. Soft-boiled eggs, junket, and boiled rice could be given, followed in a day or two by scraped beef. It should ever be borne in mind that undigested milk curds were almost as irritating as ordinary solid food. He had seen relapses occur even with an exclusively milk diet. In some a moderate elevation of temperature was maintained by starvation. The Brand bath treatment, if employed at all, should be practised with the courage of one's convictions, and not, as it often was, in a half-hearted manner. These baths should be given with the object of securing nerve stimulation rather than the reduction of body temperature. His present practice with regard to baths was to give a tub bath at a temperature of 75°F. for fifteen minutes whenever the temperature reached or exceeded 102.5°F., using frictions applied by two nurses, during the entire time the patient was taking the bath. Increasing experience had taught him the folly of adhering to rigid rules. Alcoholic stimulants should be administered fully twenty minutes before the bath, a matter of no little importance. The shivering experienced by the patient would be less if the back was first rubbed. On no account should the patient be left to shiver in the bath while the nurse was preparing the bed. If pneumonia developed, sponging should be substituted for the tub baths. He was positive that the bathing gave rise to no serious results. Except where the temperature remained constantly very high, it was well to omit one or more baths at night in order to give the patient sufficient rest. Apparently, we were as powerless to control as to foresee the occurrence of intestinal hemorrhage. When such hemorrhage took place, food should be withheld from the stomach, but if the hemorrhage were repeated at intervals of a few days it would be better to give some digested meat or peptone preparation by the mouth, or resort to rectal feeding in small quantities. The patient should be kept well under the influence of opium, and this was better effected by giving the tincture by the mouth than by hypodermic medication He had seen cases in which the suprarenal extract had apparently controlled intestinal hemorrhage in typhoid fever. particularly when occurring early in the disease. as a result of congestion. In other cases. however, he had known it to fail signally. He had abandoned the practice of applying cold locally to the abdominal wall. He had observed a number of cases in which either saline infusion or hypodermoclysis had been remarkably effective, and at times had proved to be a life-saving measure. If there was much prostration from an intestinal hemorrhage at least 1,000 cc. should be used.

Report of an Interesting Case of Typhoid Infection.—Dr. Albert W. Preston of Middletown presented this report. The case was one of hemorrhagic typhoid pleurisy, in which repeated tappings had been made. The typhoid bacilli were found in the fluid so removed. The speaker said that only about a dozen cases were reported in the literature. His case was specially noteworthy because of the occurrence of chronic nephritis. From a study of the subject, he drew the following conclusions: (1) Hemorrhagic typhoid pleurisy may be actually limited to the pleura and lung without involvement of the intestine; (2) typhoid fever may begin in the thorax and may extend later to the intestine, and (3) pleurisy may appear later in the evolution of typhoid, or during convalescence, as a mere complication or sequela.

Dr. S. J. Meltzer of New York City, in discussing the foregoing papers, expressed the opinion that the agglutination tests made in the laboratories of most boards of health were not thoroughly reliable, because it was the custom to use only a dilution of one in twenty.

Dr. E. Libman of New York City said that the colon bacillus differed from the other organisms under discussion by its power of coagulating milk. The agglutination reactions obtained with paratyphoid organisms were not a reliable aid in diagnosis, because these paratyphoid organisms would not all respond to the same blood. There was a group of pathogenic organisms resembling the typhoid bacillus in cultural characteristics, but not agglutinated by typhoid serum. For the present, cases of paratyphoid fever should be treated the same as typhoid; the etiology was not yet known, and the pathology had not been definitely determined.

Dr. W. H. Thornton of Buffalo said that the physicians of his city had been using quite extensively a substance known commercially as acetozone. There was little doubt that it was an intestinal antiseptic and antifermentative and, as a rule the cases in which it had been used had run an unusually mild course, and the duration had been apparently shortened. There did not appear to be any special contraindications to its use, and its administration. The plan that they had followed had been to make a 1-to-5,000 solution in pure water, and allow the patient to take a glassful of this at intervals of two to four hours. The taste was not particularly objectionable. The tongue was kept moist and comparatively clean.

A Study of Landry's Paralysis.—Theodore Diller reports three non-fatal cases of this disease. He suggests the following as a definition of the disorder: An infection, or toxæmia, produced by various poisons, in which the spinal cord (including the bulb), and the peripheral nerves, and especially the lower motor neurone, are attacked, and in which parenchymatous degeneration, hemorrhagic and inflammatory exudates of various kinds and degree, are usually found, post-mortem, in this portion of the nervous system. But in a few cases no post-mortem changes are discoverable, and in still others changes which are inadequate to explain the symptoms. The author holds that the term Landry's paralysis may be conveniently retained to designate cases of a certain clinical type, some of which can be made out to be poliomyelitis, others of multiple neuritis. But the term is especially useful to designate those cases which cannot be made out to be either cases of multiple neuritis or poliomyelitis, and those in which the post-mortem findings are negative.—*Journal of Nervous and Mental Disease.*

THE USE OF CONCENTRATED ACTINIC SUNLIGHT IN THE TREATMENT OF TUBERCULOSIS.

By J. W. KIME, M.D.,
FORT DODGE, IA.
SUPERINTENDENT BOULDER LODGE SANATORIUM FOR THE TREATMENT OF TUBERCULOSIS.

SUFFICIENT time has now elapsed since first I began the use of concentrated actinic sunlight in the treatment of tuberculosis of the lungs, lymph glands, and skin, to warrant me in making a report on the method, and in offering some suggestions regarding the place which light now holds in the field of therapy.

My first contribution to the literature of this subject was made in March, 1899. This, and Finsen's paper on lupus, during the same year, then embraced practically all that was known upon this subject, or, at least, all that had been published up to that time.

Since that date both Finsen and the writer have pursued their original investigations, and others have entered the field, until the literature upon this subject is now quite voluminous.

Finsen has continued his work on lupus; the *x*-ray has been utilized for the same purpose and, recently, for the treatment of epithelioma; and the writer has collected additional material for a forthcoming report on lupus; but especially have his recent investigations been extended into the more important field of phthisiotherapy by means of light.

In my former contributions I have felt a delicacy in presenting the facts which have been brought to light in this new field of investigation, fearing that prejudice which naturally holds against new ideas and new remedies, and especially since these new uses were to be aimed against those forms of disease which have hitherto been most intractable, viz., lupus, epithelioma, and tuberculosis. But recently so many able writers have commented favorably upon the work which has so far been presented, while others have also made valuable additions to our knowledge in collateral fields, that this restraint is no longer felt. So, at the present time, I feel that no apology is necessary for the presentation of this subject. It is, in fact, most surprising that this universal and omnipresent force which exercises so potent an influence all about us, and which we have always known to be absolutely essential to our existence, has so long been neglected as a remedial agent.

Its two principal correlative forces, electricity and heat, have from the beginning of medical history been employed for the relief of suffering, but this important member of the trio has been passed by with singular indifference.

Enough is now known that we may safely say that light, in one form or another, is proving the specific treatment for epithelioma and lupus, two affections which have always proven most invincible to all known methods. In lupus vulgaris, and in lupus erythematosus, concentrated actinic sunlight is a specific remedy. After the deeper tissues are involved, and when necrosis of the underlying bones exists—when, in fact, the lupus has assumed a more malignant type, as practically all these advanced forms of lupus do, then the light exercises a less marked influence, and, up to the present time, it is extremely doubtful if any known agent will arrest the course of the disease.

But it is to the therapy of laryngeal and pulmonary tuberculosis that the present contribution is made.

In laryngeal tuberculosis light is the most efficient remedy yet tried; and this is as we would expect it, judging from the known effects of light on lupus, since the laryngeal structures are so readily accessible to its influence.

In my published reports on "The Penetrability of Actinic Light," I have shown that light may be made to pass very deeply into, and even through, the adult body (MEDICAL RECORD, October 13, 1900; *Scientific American*, September 29, 1900; *Photographic Times*, October, 1900). Hence light of great intensity must reach to the depth of the larynx.

Laryngeal tuberculosis has, in my experience, yielded most readily to treatment by means of light. After a few applications the pain disappears, the aphonia diminishes, and gradually the voice sounds reappear.

As the laryngeal cases which have fallen under my observations have in each instance been accompanied by pulmonary tuberculosis, I report them in connection with the full case reports.

In all, sixty cases of pulmonary tuberculosis have been treated, or are still under treatment. These have either been in my own practice at Boulder Lodge Sanatorium, at Fort Dodge, or in that of my associates at Denver, Col., and at Salt Lake City.

Of those treated, in twelve the disease has been arrested; in eleven more the improvement has been so marked that a practical arrest has been effected; one has not improved; five have been dismissed, after a few days' rest, as incurable, and thirty-one are still under treatment, most of them showing satisfactory improvement.

I prefer the term "arrested" to "cured," although to all possible means of physical diagnosis the cure has been complete.

Before taking up a report of cases in detail, it may be well to call attention, briefly, to the manner in which the light is used.

The reflector made use of is thirty-six inches in diameter, and is so constructed that all the light falling upon it is focussed three feet in front of it upon a spot eight inches in diameter.

An intense blue light, which is rich in actinic rays, is thus utilized. This is thrown upon the bare chest of the patient for from two to three hours each day when the sun shines. Although this light is quite warm, it does not produce blistering of the skin. Direct sunlight less than one-half as hot produces extensive blistering of the skin. The illustration shows a number of patients being treated on a roof-garden.

TREATMENT ON ROOF GARDEN, FORT DODGE, IA.

The light thus used brings about the desired result in one or both of two ways:

1. The powerful light penetrates the chest wall and reaches the diseased structures, and there produces the same results that are noted in external tuberculosis (lupus). The light produces engorgement of the parts with blood; this influx of blood brings increased nutrition to the part and gradually repair is effected. The light also has an inhibiting effect upon the bacilli.

2. The effect of the light upon the blood which circulates through the skin must be very great. This blood finds its way immediately to the parts diseased. What effect, in a depurative way, this light may have upon the blood has not yet been discovered, but it is certain that a high percentage of the light is absorbed by the blood. The clinical effects are prompt and easily apparent. Hope is stimulated beyond that under any other treatment which I have ever witnessed.

In cases that are practically *in extremis* this hopefulness is painful to witness. In the case of one young man, reported below, it was plainly manifest that he would not go through the night. I told him that he would not see the light of another day, and, as he was alone in the sanatorium, I asked him to make his final business arrangements. This he did, and then immediately began telling me what he was going to do when he got well. In ten hours he was dead. This great faith and the determination to follow out in detail the use of the light and the accompanying hygienic and dietetic arrangements are powerful factors for good in cases that are not too far consumed by the raging fires within.

The appetite and all the bodily functions improve, and within a few days a new interest in life is manifest in every act. Of course, there is a limit beyond which no human power can hope to prevail. There is a time when every case of tuberculosis is curable, but this is not in the last part of the last stage of the disease. Early recognition, and early application to the disease of those things which are of value, will bring back life and health and strength. But hope does not lie in the direction of polypharmacy. Light, air, diet, and hygiene are the essential factors, and beyond these nothing is needed except constant, intelligent medical supervision.

I would not have it understood that light alone is made use of in the treatment of tuberculosis. Life in the open air and sunshine, good nutritious food, forced feeding, freedom from dust and smoke, a hygienic life, every act under the eye of the physician or of his specially-trained nurses, medicines as indicated for intercurrent symptoms of importance—these are the factors relied upon, and the factors which contribute to the end attained.

But without the light I should be greatly handicapped, and far less could be accomplished for those who come for treatment. I admit that the psychical effect of the light is of value, but it is not psychics that cures external tuberculosis which from the first treatment begins to improve, and it is the same power which, externally applied, cures lupus that, internally applied, brings about a like result in internal tuberculosis, The visible changes that take place in lupus are engorgement of the parts with blood, a cleaning of the surfaces by falling off of the crusts, a healthy, granulating surface, and a beginning cicatrization.

In laryngeal tuberculosis, which is not different from external lupus, except that it is differently situated, similar changes take place until healing is complete.

In pulmonary tuberculosis there is usually, for the first few days or weeks, an increased dyspnœa. This is, without doubt, due to engorgement of the lung tissues with blood. Later, this difficulty of breathing disappears, the dulness lessens, and in early cases normal resonance returns.

Case I.—B. W., Missouri Valley, Ia.; female, aged seventeen years; family history good. Disease of two years' standing; percussion, right, normal; left, dull at apex; loose râles over upper part of left; pulse 120, temperature 105°; cough dry and constant; some expectoration; bacilli present. Has been at Boulder, Col., for six months; has had two quite profuse hemorrhages; weight ninety-two pounds, former weight 108; appetite poor, menstruation suppressed four months. Began treatment October 13, 1900. Improvement was marked and rapid. On August 28, 1901, I made the following entry: "No signs or symptoms of tuberculosis present; temperature normal, respiration 20, pulse 85, weight 97. Menses normal; feels perfectly well; no cough or expectoration, and no bacilli. Advised taking up two studies at school." This patient gradually increased her school work, and graduated from the high school in June, 1902. Perfectly well at the present time, and to all appearances the cure remains complete. Weight 100.

Case II.—Miss H. J., Worthington, Minn., aged seventeen years; family history very bad; a number of the immediate family dead from tuberculosis; slight dulness at right apex, and moist râles in same region; slight cough and expectoration; bacilli present in small numbers; temperature 100°; night sweats; weak and listless; weight 133. Began treatment March 6, 1901. Returned home, improved in every way, June 5, 1901. Her family physician wrote me, under date of August 31, 1901, stating that he then found no evidence present of the disease, and adds, "I am convinced she is permanently cured." Patient well at time of this report, June, 1902.

MEN'S TREATMENT ROOM, DENVER, COL.

Case III.—Miss M. J., Avoca, Ia., aged twenty-eight years; two sisters dead from tuberculosis; noticed failure of health in April, 1901, soon after the death of a sister; feels weak; has night sweats, cough, and slight expectoration; menses regular; bacilli present; weight 123, former weight 140; pulse 86, temperature 99.6°; appetite poor. Began treatment July 31, 1901, remained twelve weeks, and gained twenty-three pounds; at time of this report, June, 1902, patient perfectly well and weighs 163 pounds, twenty-three pounds above her usual weight. This was an incipient case, and shows the great value of early treatment in this disease.

Case IV.—Miss L. D., Rock Rapids, Ia., teacher, aged twenty-three years; referred as dernier ressort, there being little prospect of life being extended more than a few weeks; unable to take more than a few steps at a time; health began to fail three years ago; two sisters dead from tuberculosis at ages of twenty-two and forty; cough irritating and constant; appetite poor; night sweats; menses suppressed for several months. Flatness over apices of both lungs; loud moist râles; pulse 120, temperature 102°. Much expectoration and bacilli numerous; weight eighty-nine pounds, former weight 120 pounds. Began treatment January 26, 1901, and remained until October, 1901. Weight increased from eighty-nine to ninety-seven pounds, and menstruation returned in August, since which time it has been normal; night sweats disappeared in May; can walk a mile without fatigue; cough much improved; percussion sounds normal and no râles. Bacilli still found when patient was compelled, for financial reasons, to return home. At the time of this report she is still improving and with good prospects of ultimate recovery.

Case V.—Miss H. G., Odebolt, Ia. aged twenty-nine years; mother and one brother dead from tuberculosis; has had cold abscesses over various parts of the body for three years, accompanied by necrosis of tibia, clavicle, sternum, ribs, and scapula. Weight 103, former weight 130; temperature 103°, pulse 116; menses suppressed for four months; bronchial breathing over left side; left side shrunken from destruction of ribs on that side; respiration 32; placed in sanatorium to remove source of danger from friends. This patient remained twelve weeks. During this time she gained thirty pounds, her wounds were healed, and she returned to her home, to all appearances, entirely well.

Case VI.—Miss A. A., Fort Dodge, Ia., aged twenty-seven years; domestic; mother and one sister dead from tuberculosis; patient very tired; soreness of lungs; constant cough and considerable mucopurulent expectoration; many bacilli; night sweats and fever; temperature 103°; menses suppressed for three months; weight 113, former weight 120; flatness over upper part of left lung, bronchial breathing, and loud moist râles; right, normal. Remained three months; improved in every way; weight increased to 128. No night sweats or chills, and but little expectoration. Bacilli still found. Returned to her work, and for the past year has continued at work.

Case VII.—Miss C. B., Ackley, Ia., aged twenty-four years, family history free from tuberculosis; past two years spent in Colorado; tires easily; not been well for ten years; cough dry and but slight expectoration; night sweats and chills; has had two attacks of pleurisy; weight 109; very few bacilli found; dulness and bronchial breathing at apex of left lung; no râles; evening temperature 99.6°; pulse 85, respiration 28; remained at sanatorium three months and gained twelve pounds and is much stronger. Bacilli still present when she returned home. This patient also had morphia habit, which was relieved while here. No report since returning home.

Case VIII.—Miss A. F., aged twenty-five years, Popejoy, Ia. Health began to fail in fall of 1900; cough appeared in March, 1901, followed by enlargement of the cervical glands; one gland suppurated and was incised; hemorrhage in April, also in August and September, 1901; has night sweats, chills and fever; has had considerable diarrhœa; menses suppressed for two months; present weight 118, former weight 140; temperature 99.5°; pulse 100; a number of glands on both sides of neck enlarged; percussion sounds normal, dry râles near lower end of sternum; respiration 36; very pale, almost chlorotic; bacilli present. Began treatment November 1, 1901; during her stay a gland on right side of neck suppurated and was incised and curetted; menses reappeared in December. Returned home February 12, 1902; no physical signs, except audible expiratory murmur on both sides. Cough very much improved, no sweats or chills, complexion good; weight 140 pounds. Examined June 1, 1902; is well, but still has two or three small glands in the neck.

Case IX.—E. B., Fort Dodge, Ia.; aged twenty-four years; father dead from tuberculosis; two paternal aunts dead from tuberculosis; trouble began two years ago with a cold; has had some fever, and cough for a good while; present weight 138, former weight 140; considerable expectoration, creamy and gelatinous; some pain in chest. Dulness at left apex; sibilant râles at left apex; hoarse most of the time; pulse 80; temperature 99.8°; dipplococcus of pneumonia found, no tubercle bacilli; Remained until April 24, 1902; weight then 148; looks well and feels well. Returned to the farm; temperature normal, pulse 76. Disease arrested. Laryngitis disappeared early during treatment.

Case X.—Miss L. D., Burnside, Ia., aged thirty years; admitted October 9. 1901; family history free from tuberculosis; patient has had hemorrhages for fifteen years. has had cough for same length of time; hemorrhages more severe for past three years; now almost daily; three weeks ago bled two quarts; has some chills and night sweats; menstruation slight and irregular; percussion sounds tympanitic and of emphysematous character; chest prominent and ribs widely apart—has chronic pulmonary emphysema. Hemorrhages occurred daily after admittance during the first week, averaging half a teacup of frothy blood; pulse 100; temperature 99.6°; respiration 24; a few bacilli found. Weight 103. On October 11 had hemorrhage of six ounces, was then put to bed for two weeks, carrying her to roof-garden for treatment. Remained until December 1, 1901. Hemorrhages have completely ceased, weight increased to 111 pounds, and patient is able to walk several miles each day without inconvenience. Temperature and pulse were normal. This patient was doing remarkable well, but was compelled to return home on account of private matters.

Case XI.—J. M., Riceville, Ia.; admitted December 30, 1901; little known of family; has been in Oregon and has used the Hoff treatment; severe hemorrhage in March, 1899; two smaller hemorrhages since; weight 124, former weight 130; has had severe chill each day since July, followed by fever and sweating at night; chills about 3 P.M., sweats toward morning; cough loose and considerable expectoration; tubercle bacilli and dipplococcus of pneumonia found; pulse 120, temperature 103° and reached 105°. Has considerable pain in knees and ankles; percussion sounds normal, except slight dulness over middle lobe of left lung, bronchial breathing at upper part of left. Sg. of urine, 1,025; no albumin, pus, or sugar. Thinking a malarial complication might exist, quinine, and, later, methylene blue were tried without effect; plasmodium malariæ not found in blood. Put on rest treatment last few days of his stay and began to improve. Went home February 3, 1902. No subsequent report.

Case XII.—Mrs. J. D. C., Humboldt, Ia.; aged thirty years; paternal uncle died of tuberculosis; until five years ago patient weighed 120 pounds, now weighs 175 pounds; health began to fail July, 1901; soreness and bronchial breathing at upper part of left lung; some cough and expectoration; bacilli present, temperature 100°; pulse 90; remained one month, cough and soreness disappeared. Reported June, 1902, in perfect health.

Case XIII.—G. A. Y., Harlan, Ia.; aged fifty-two years, farmer and merchant; no tuberculosis in family. Had influenza two and one half years ago, subject to colds since then; confined to bed part of the time; considerable loose cough and mucopurulent expectoration; temperature 101, pulse 90; diarrhœa at times since 1897; probably, primarily, intestinal tuberculosis; former weight 155, present weight 122; râles over both sides; percussion sounds not much altered; hoarse constantly for two years; diarrhœa now nearly all the time, some dry râles over upper part of left lung. Remained from September 1 to November 7, 1901; at time of going home weighed 136 pounds, a gain of thirteen pounds. Respiratory murmur normal; no diarrhœa for past six weeks; temperature normal, pulse 90; some bacilli still found; report May, 1902, remains in about the same health as when he returned home. Disease arrested.

Case XIV.—Mrs. L. W., Harlan, Ia., aged twenty-eight years; admitted August 31, 1901; mother dead from tuberculosis; three sisters and one brother living, but all delicate. Patient sick four years; has had cough and fever; considerable expectoration; bacilli present, also found in urine; average weight 115 pounds; present weight ninety-four pounds; menses suppressed three months; has had pleurisy; night sweats; diarrhœa for three months; chills; temperature 103°; has been in Oklahoma, Kansas, and Colorado; now suffering from pulmonary and laryngeal tuberculosis; voice completely lost from October to February, 1901; has had slight hemorrhages; diarrhœa quite severe after admission; slight dulness over upper part of left lung; bronchial breathing and loud moist râles over same region; quite hoarse; remained until October 10, 1901. Has had chill nearly every forenoon. Temperature has ranged from 101° to 105°. Very weak; pain in region of bladder. Hoarseness disappeared, but other symptoms not improved. In last stages of more or less generalized tuberculosis. Returned to her home with letter to family physician requesting notice of termination of the case. Died about February 15, 1902.

Case XV.—Miss L. M., Vinton, Ia., aged twenty-two years; admitted December 8, 1901; occupation, trained nurse; mother dead of tuberculosis at age of twenty-eight; patient took cold about the middle of August, 1901; has been hoarse since August, and now has almost complete aphonia; in August had temperature of 102.5; tires easily, and has aching of limbs; night sweats and some chills; coughs a great deal, cough dry; considerable expectoration in morning; some soreness in chest; no loss in weight; former weight 125, present weight 122; bacilli present; morning temperature slightly subnormal, evening temperature a little above normal. Dulness at right apex, extending below second rib; audible expiratory murmur; remained until February 27, at which time had appearance of perfect health; weight 132 pounds. But little cough and expectoration. A few bacilli still found, temperature practically normal, but heart a little fast, about 90. Returned May 5, 1902. Can find no evidence of tuberculosis on most careful physical examination; dulness at right apex has entirely cleared up, but still coughs some, and there is slight expectoration; bacilli are found; has been nursing, and has overtaxed her strength; respiration normal, pulse 90; weight now 125. At the end of June, 1902, after being under observation for six weeks, is very much improved, and disease now appears to be arrested. Temperature is normal, and all danger is believed to be past if a proper mode of life be maintained.

Case XVI.—Miss A. L., Clarksville, Ia., aged twenty-two years; admitted November 21, 1901; maternal aunt died of consumption; patient's former weight 112, now 80; first noticed cough in February, 1901, cough loose from first; considerable expectoration, sweats since March; temperature 101°, pulse 110; diarrhœa during past two weeks; menses suppressed since May; has had chills since February; has had three small hemorrhages; percussion sounds on right side not much altered from normal; loose râles over entire right lung; on left, dulness over middle lobe and loud moist râles, with gurgling; some nausea and vomiting; December 14, weight eighty-four pounds.

This patient was suffering from a rapid form of pulmonary tuberculosis; she was very frail and emaciated. She remained under care one month. During this time she gained four pounds in weight, and her temperature declined one degree, evening average, over time of admission.

While she showed improvement, prognosis was unfavorable, and although no report has been received, it is more than probable that she has since died.

Cases XVII, XVIII, XIX, and XX were all very similar to Case XVI. The patients were very far advanced, and were kept under observation but a few days. They were permitted to rest and return home, and all are now dead.

Cases that are hopeless are not permitted to remain longer than to rest for the return trip to their homes. They are entered, and histories are taken for reference, but they are not counted in making up percentages, as they are not received with any view toward effecting a cure.

Cases XXI and XXII were both hopeful ones, but neither of the patients would consent to the necessary requirements of treatment; both had been reared in luxury, and preferred to die in luxury rather than to accommodate themselves to the conditions necessary for a return to health.

Case XXIII.—E. L. K., Memphis, Neb., aged thirty years; pharmacist and teacher; family history good; present weight 129, former weight, 136; primary tuberculous infection right upper lobe; first symptoms in fall of 1901; cough dry, frequent, frothy expectoration; bacilli present; night sweats, chills, and diarrhœa; no temperature; respiration 22, pulse 70; tongue furred, appetite fair; anæmia marked; dulness over upper right lobe and loud mucous râles. Began treatment March 1, 1902. On June 1, 1902, examination shows improved general nutrition; all outward signs of the disease have disappeared; slight roughness of breath sounds over right apex in front, otherwise normal vesicular murmur over entire lung area; respiration 18; cough and night sweats have disappeared; appetite good; sleeps well; no râles; has gained eleven pounds, and now weighs 140 pounds. Returned to work.

Case XXIV.—S. E. B., Michigan; cigarmaker, aged twenty-nine years; father dead from tuberculosis; cough began about July, 1901; one limb amputated for tuberculosis of bone; night sweats; has lost ten pounds. Has much headache and diarrhœa; is weak and nervous; interscapular pains and irritable bladder. Various râles over upper part of both lungs; coughs constantly, and has considerable expectoration, frothy in character. Respiration 26, pulse 80; tongue furred; appetite fair; marked anæmia; bacilli present; dulness over right upper lobe; bronchial breathing. Entered March 14, 1902. After one month, gained thirteen pounds; feels well; anæmia much improved; coughs but little, and but little expectoration. Went to work at his trade.

Case XXV.—G. W. G., New York; bookbinder, aged fifty-two years; history of overwork and confinement; four years ago had measles, followed by tonsillitis; tonsillotomy done; cough, hemorrhage, night sweats, and gradual decline from 140 to 117 pounds; appetite fair; is irritable and despondent; asthmatic breathing; râles numerous over right upper lobe, principally moist. Expansion diminished on right side. Began treatment March 13, 1902; June 1, improvement general, and has gone to work.

Case XXVI.—N. B., Winnipeg, Manitoba; aged forty years; farmer; first symptoms twelve years ago; cough troublesome and frequent; expectoration mucopurulent and frothy; has had two or three light hemorrhages; night sweats off and on for past seven years; chronic laryngitis; former weight 188, present weight 179; respiration 24, pulse 64; tongue furred, appetite fair; facial neuralgia on right side and chronic otitis media; dulness at right apex; pleuritic friction murmur at upper part of left lung; râles few, principally dry. Began treatment March 20, 1902. June 1, 1902, much improved, less cough and expectoration; has gained six pounds; laryngeal trouble gone; still under treatment.

Case XXVII.—G. W. C., Jr., Elgin, Ill., aged twenty-one years; never strong; father has tuberculosis; has had pneumonia and rheumatism several times; cough and considerable expectoration, yellow and foul smelling; mixed infection present; râles numerous, and pleuritic friction sounds; dull over consolidated portions and tympanic over cavities; respiration 23; night sweats and pain in chest. Began treatment March 25. June 3, no night sweats, appetite improved, strength increased. Has gained five pounds. Still under treatment.

Case XXVIII.—G. W. C., Sr., Elgin, Ill.; merchant; one year ago noticed continuous cough and expectoration; has pain in chest and difficulty in breathing; troubled very much with hemorrhoids; respiration 26; moist bronchial râles, large; has lost some in weight; began treatment March 22, 1902. June 15, 1902, marked improvement, breathing much better; has gained ten pounds in weight and hemorrhoids are well.

Case XXIX.—W. A. G., Iowa City, Ia., farmer, aged thirty-one years; first noticed failure of health in June, 1901; former weight 155, present weight 128; cough very troublesome, slight hemorrhages; night sweats, chills and fever; bacilli in abundance, appetite poor; râles over apices of both lungs; respiration 32, pulse 120; can walk but a short distance. Began treatment March 30, 1902. June 5, walks eight blocks for treatment, and shows improvement in every way. Still under treatment.

Remaining cases are still under treatment, and while nearly all are showing improvement, they have not been under observation long enough to warrant a review of changes which have occurred.

From my experience and observation concerning the use of powerful doses of actinic light, derived directly from the sun itself, the dosage being given daily in the open air, except in the coldest weather, I am convinced that it is at the present time the most important therapeutic agent in the treatment of tuberculosis. Without it many cases that come to me for treatment would at once be dismissed as entirely without hope or encouragement, which soon begin to show improvement, and in whom the disease is eventually arrested.

Since the publication of my paper in the Medical Record, October, 1900, describing the technique of photographing through the human body, others, both in this country and in Germany, have made similar experiments with results the same as originally found by myself. In at least one of these papers the author, two years after the publication of my paper, claims that he has first demonstrated the penetrability of the human body by the actinic ray.

Pure actinic light is invisible to the eye and lies beyond the violet rays of the solar spectrum and is more refrangible than are the visible rays of the sun. We are as yet unable to harness these rays alone for use, but since the violet band of the spectrum, which lies next to the pure actinic rays, is rich in this chemotactic light, we may, by use of the violet ray, obtain a light which is very powerfully actinic, and which contains but few of the heat rays which lie at the opposite end of the solar spectrum.

It is this ray which produces the chemical changes of light. Its principal and most powerful source is the sun. It is the ray used in photography, and the value of actinic light obtained from the sun over that from artificial light is here best shown. While the electric-arc light may be made use of in photography it is always the light of necessity and not of choice.

The writer is very strongly of the opinion that light taken directly from the original source of all light is very much to be preferred over that from any other source.

As to the action of actinic light: (1) The human body is translucent to it. (2) The irritant action of the light on the living body cells is a direct stimulus to them. (3) A high percentage of the light is absorbed by the tissues through which it passes. (4) The light which is absorbed by the cells of the body produces definite chemical changes in them. (5) Actinic light inhibits and destroys bacterial life.

As none of the structures of the body are beyond the reach of strongly concentrated actinic light, none of its tissues lie beyond the therapeutic application of the light.

SOME EXPERIMENTS WITH PARAFFIN.

By A. E. COMSTOCK, M.S., M.D.
ST. PAUL, MINN.
PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY, UNIVERSITY OF MINNESOTA.

Considerable has been written of late concerning the subcutaneous injection of paraffin for the correction of deformities, and in other surgical procedures. So successful have been the reports, that all doubt as to the possibilities of harm to the patient, if properly used, has been eliminated.

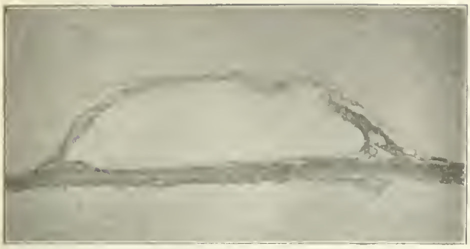
There is a great difference of opinion as to what the melting point should be. I thought, therefore, that it might be interesting to present the results of a few experiments I have been performing with paraffin injections at different melting points; and also to show a few of the microphotographic views which have been prepared, illustrating the development of the new tissue that perforates the imbedded paraffin, forming a new, firm, and well-organized mass. I wish to give credit to H. D. Newkirk for the excellent preparation of the slides, which have required a great deal of time and skilful technique; also to Mr. G. Schmidt for the careful preparation of the microphotographic views. Both of these are in the junior class at the University.

As is known, paraffin is a coal-tar product; first in the hydrocarbonic series, with a general formula of C_nH_{2n+2}, colorless, odorless, non-toxic, and nonabsorbable, with a melting point of 120° to 180° F.

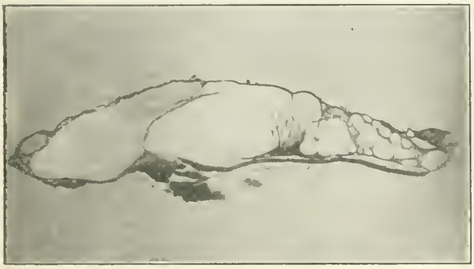
It has a wide range of use in the commercial, and a promising field in the surgical world. The subcutaneous use, if outside of the vessel walls and not in large quantities, produces no ill effect further than local inflammation and swelling for a few days, reaching its height in about one week, and then gradually becoming normal.

The preparations I used were a mixture of the soft commercial paraffin, having a melting point of 120° F., and white cosmoline, melting at about 100° F. I made mixtures of these so as to have samples melting at 102°, 104°, and 110° F. These were sterilized by boiling for thirty minutes over a flame. The beaker was protected by an asbestos screen, so as not to burn the paraffin; after this it was decanted, so as to leave all sediment behind, and was then ready for use.

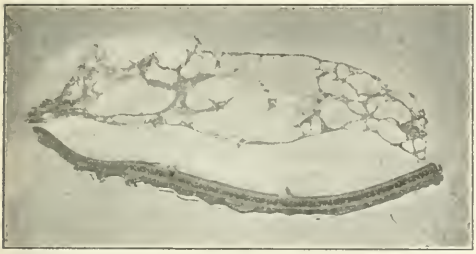
The syringe I find best adapted is a metallic aspirator, because it is large enough to hold the heat, and stronger and better in every way. The



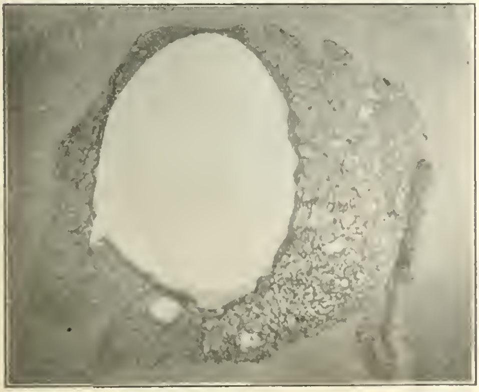
No. 1, A.—Temperature 102° Two weeks; ear. × 7



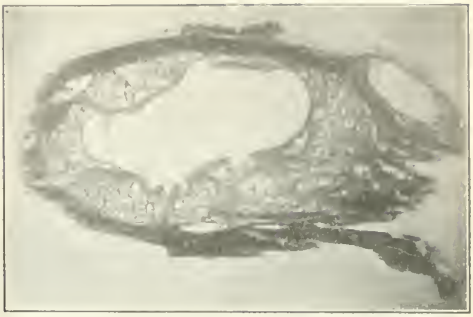
No 2, A.—Temperature. 110° Four weeks; hip. × 7.



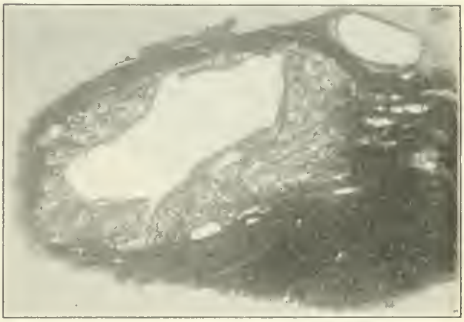
No 3, A.—Temperature, 104° Six weeks; ear. × 7.



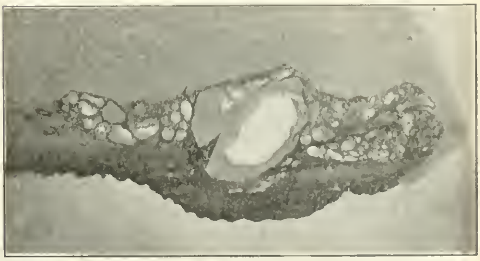
No 8 A—Temperature 110° Sixteen weeks; hip. × 7



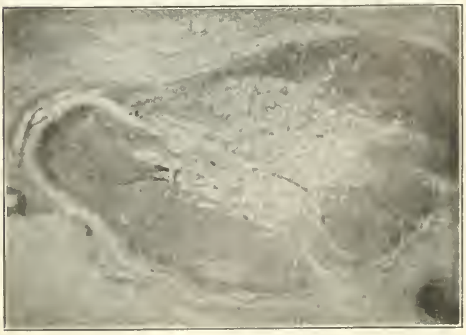
No. 4, A.—Temperature, 110°. Eight weeks; hip. × 7.



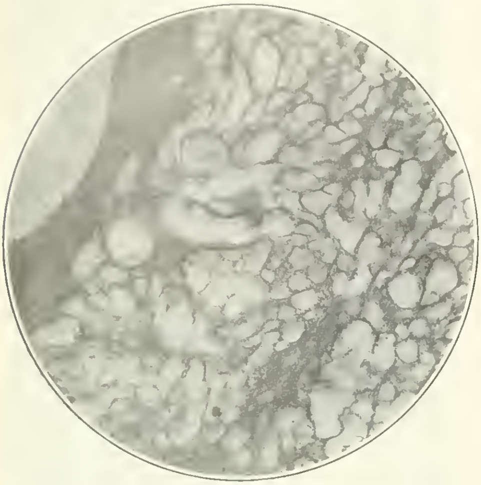
No. 5, B.—Temperature, 110°. Eight weeks; hip. × 7



No. 6, B—Temperature, 104° Fourteen weeks; ear. × 7.

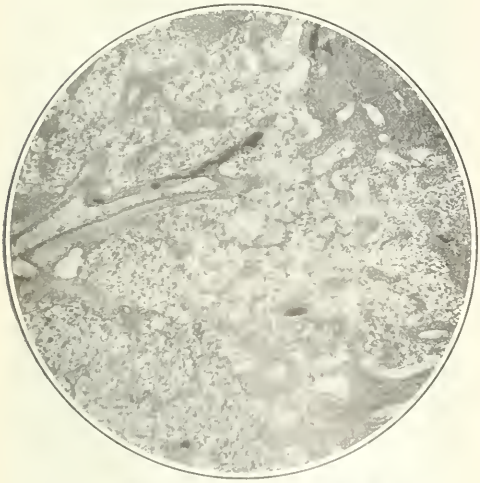


No 7, B.—Temperature, 110°. Sixteen weeks; hip. × 7 needle must be of a fairly large size, because it is difficult to force the paraffin through the smaller ones. It must be a perfectly-working instrument, with a plunger, and all joints very tight, for the reason that melted paraffin goes every road but the right one.

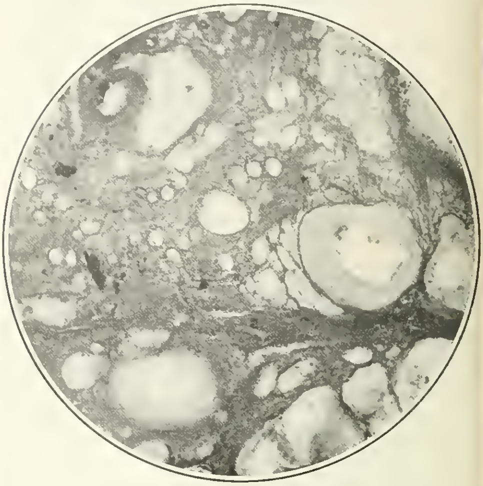


No. 7. A.—Temperature, 110°. Sixteen weeks; hip. × 65

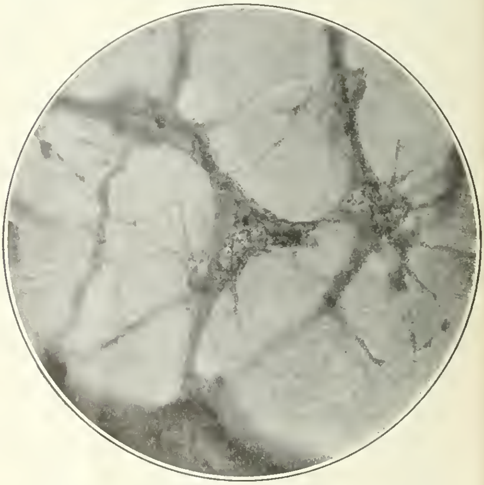
After the instrument has been filled with melted paraffin, it is left in hot, sterile water until ready for use. After the parts have been thoroughly sterilized, the instrument is taken from the water; then, forcing out the air, and waiting a second until the paraffin becomes a thready mass, as it comes from the opening, the needle is inserted into the cellular tissue to the point where you wish to begin the elevation. Then gradually inject the paraffin, withdrawing the needle as you do so. Care must be taken at this point, as the paraffin cools rapidly in the needle, making it come out unevenly and in spurts unless the pressure on the piston is firmly controlled. When this occurs, it is liable to bulge out and separate tissue where it is not desired, thus destroying the symmetry of the part. The mass now presents a doughy feel, and can be moulded, to a certain extent, into form, unless it is where there is too great tension on the skin surface, when it will assume its own form and flatten out.



No. 7. B.—Temperature, 110°. Sixteen [illegible]



No. 6 B.—Temperature, 104°. Fourteen weeks: ear. × 65.



No. 3.—Temperature, 104°. Six weeks; ear. × 235

This is more especially true in the loose, subcutaneous tissue, and when the paraffin is at a low melting point.

In one instance, experimenting on a rabbit with paraffin which had a melting point of 104° F., it remained liquid, and presented a soft, fluctuating mass, for about one week, gradually becoming firm, and afterward organizing. I attributed this to the rise of temperature, which none of the others had.

This same animal had an injection of the higher-melting paraffin, which held its form, not being disturbed by the temperature, and therefore made better progress. I believe it is because it was stationary, and thus did not destroy, by change of form from pressure or motion (as easily as did the soft), the little tissue cells in their attempt to penetrate the foreign substance. In all cases I have noticed a certain amount of apparent shrinking as the mass hardened and organized, which is probably due to absorption of the small amount of oil which is in the paraffin, leaving only the solid residue. This change leaves minute, softened openings, through which the little tissue cells make their first entrance in their attempt to bring into the fold this stranger from the material world.

The microphotographic views I have here represent the paraffin injections in intercellular and muscular tissues at different temperatures, and for periods varying from two weeks to four months; and show the comparative development. (All specimens marked "A" are those from which the paraffin has been dissolved; those marked "B" have the paraffin still in place.)

1. The first is two weeks old, being injected between skin and cartilage of the left ear; melting point, 102° F. In this we find the mass quite firm; all signs of active inflammation have subsided, and the mass appears encapsulated, with here and there a few giant cells at the periphery, showing the paraffin to be the irritant for the development of new tissue.

2. In this we have a specimen which was injected into the loose tissue of the flank. It had a melting point of 110° F., and shows the development which has taken place in four weeks' time. We find, also, numerous giant cells, fibroblasts, and small capillary growths following the connective tissue development; the thinner parts of the paraffin are entirely perforated by new tissue, the thicker parts remaining as yet unchanged. I should say that fully one-third of the new body has gone through the primary stages of organization.

3. Is a specimen from the ear with a melting point of 104° F., and six weeks old. This shows a larger number of fibroblasts, which have permeated the paraffin, and which have thrown out numerous spindle-shaped processes, showing the further development of connective tissue, which is conclusive evidence of the beginning organization of the mass. In this we see about one-half of the foreign body that has become organized.

4. Is a specimen eight weeks old, with a melting point of 110° F. The paraffin was injected into both cellular and muscular tissue. Three-fourths of the mass is organized. The connective tissue has thoroughly formed, running between and surrounding the paraffin particles to such an extent that one might think the paraffin entirely absorbed; but such is not the case. To illustrate, I will present one of the microphotographic views (No. 5) of the same specimen from which the paraffin has not been dissolved, showing how much more densely the tissue appears with the paraffin in place. It was found necessary, on this account, to take out the paraffin in the earlier specimens to show better the tissue changes.

6. Is a specimen fourteen weeks old, and was somewhat of a disappointment. The melting point was 104° F., and injected at the base of the ear. The small particles of paraffin are larger and more irregular than the other specimens of the harder variety, with still quite a large mass in the center as yet unchanged. The one seems characteristic of the paraffin with a low melting point, and in no instance have I found it so finely organized as those of the higher, while the other (or centrally unorganized bodies) are practically the same in both.

7. Is a sample showing this point nicely when compared with the above. This has a melting point of 110° F.; was in the body sixteen weeks; and shows a full development which seems to have taken place. The animal was injected, before killing, with chrome yellow gelatin solution, which stained some of the blood vessels of the new tissue, and is represented by the dark lines and specks.

The minute development shows much plainer in the microphotographic views of the higher powers, a few of which are given you here simply to show the structures when magnified by a stronger lense. These views are taken from some of those already described, as can be recognized by the markings.

In all cases in which paraffin was used at 102° F., the animal died within two weeks' time, hence the specimens of that temperature are limited (death being caused by thrombosis); consequently there is a break in the comparison of the development of the soft variety, with those of the hard, after the second week. It demonstrated its point, however, and the development in the other cases can be successfully observed. It will be remembered that the temperature of the rabbit is about 102½° F., hence the lower-melting variety of paraffin was slightly less than the bodily temperature. In all of the other cases, with the higher-melting point, no unpleasant results were experienced whatever.

"Jukuff of Strausberg found, in animals, that unpleasant and fatal results from subcutaneous injections occurred only when one-tenth of the bodily weight was used; and in cases in which the melting point was below the bodily temperature. In the latter the post-mortem examination revealed lung emboli and thrombi in small veins."

From this, and my own experience, I would draw the conclusion that paraffin must be used where it will be at all times above the bodily temperature, in order to prevent any danger from emboli forming. Furthermore, from Jukuff's experiments, we see that the toxic dose would be anywhere from ten to fifteen pounds for the average person, so there can be little danger from over-dose, for no surgeon would attempt by this means simply to increase the avoirdupois of his patient.

In selecting the melting temperature point, for surgical uses, allowance will have to be made for the difference in temperature between the rabbit and human species, which is about 4° F., making a choice of 106° or 107° F., the best for use in subcutaneous injections, for the reason that it gives a substance firm enough to hold very well its form, especially when confined by the surrounding tissue; and at the same time, with a melting point out of reach of the system at all times. Furthermore, the difference from congestion and inflammation between the different temperatured paraffins was scarcely perceptible. The harder paraffin, when it reaches the thready consistency, as it does coming from the needle, causes no more pain or local irritation than the lower temperature; and in comparison of the specimens here a firmer, finer, and better tissue will be found in the paraffin with a melting point at 110° F. As for a local anæsthetic, the pain is so trifling, if properly done, that a 1 per cent. solution of cocaine at the point of puncture is all that is necessary. I do not believe in filling up the space with any form of liquid before using the paraffin, as some have advised, because it disguises the deformity, and makes it more difficult to tell exactly how much paraffin should be used, and is simply an unnecessary step.

On account of the natural shrinkage, you may find it advisable to use more than one injection; if so, it might be well to make it in two or three weeks, and either a little above or below, or to one side, of the primary injection, so as to leave some of the tissue elements between the two masses; and thus prevent the destruction or retarding of growth of the new tissue cells, which are beginning, about this time, to perforate the paraffin. From the rapidity of the tissue growth, shown by these experiments, we calculate that at least four months are required to fully organize specimens of this size, which were two centimeters in length, one and one-half in width, and one in thickness, as they appeared in the specimens prepared for section.

This is not so, however, in all cases, as, in some of the specimens of the same age and melting points, the central portion became capsulated after three-fourths or more had become organized, and was retained within a membrane which is distinctly visible. This also occurred in specimens of other temperatures, and under the same conditions.

But in no instance have we a specimen that is not at least three-fourths organized, and, perhaps, time would have completed it.

No. 8 is a photo of this capsulated portion. Both conditions have been given, take them for what they are worth; personally I am quite sure that the latter in no way detracts from the promised usefulness of this procedure.

As it has been my pleasure to present these few evidences here to prove the fact that we have a substance which will fill in spaces of lost tissue, and not remain entirely a capsulated foreign body, but become a bridge-work, and, in fact, a part of the new tissue, I leave you to ponder and to draw upon your own imagination for the various uses and ways this may be of service; and the benefits that may be derived therefrom.

The evidences, however, are sufficient to warrant an extended trial of this branch of surgery, for it seems to me we have been given a substance which, although discovered by accident, fills a long-desired want.

416 New York Life Building.

THE USE OF THE CLINICAL THERMOMETER AS AN AID IN QUARANTINE INSPECTION.

By A. H. DOTY, M.D.,

HEALTH OFFICER, PORT OF NEW YORK

Experience has shown that in the examination of passengers and crews of incoming vessels the requirements of modern sanitation are not fulfilled by the method of inspection which has hitherto been employed. I refer to a visual examination in conjunction with the statement of the person under observation. As a rule, it is difficult to secure frank statements regarding their physical condition from those who are ill on arrival at Quarantine, if they have reason to believe it may cause their detention. Aside from this, sailors and others who are subject to hardship and exposure, pay little or no attention to mild attacks of disease, which do not actually interfere with their work. Furthermore, in the examination of persons held at Quarantine there is a class of cases of infectious disease to be carefully guarded against which constitute a most serious menace to the public health, viz., mild, ambulant, or convalescent cases. These are not always promptly or easily recognized, and are responsible for many outbreaks of infectious disease, the origin of which are unknown, but which are commonly and erroneously believed to be due to the transmission of infection through the medium of clothing, bedding, etc. A passenger, or a member of the crew of an incoming vessel, may report on deck for examination and appear in good health, while suffering from an infectious disease, either in its initial stage or in a mild form. Therefore, it is necessary to surround an examination of this character with every safeguard which is reasonable and practical. Even in the early stage, or in a mild form of an infectious disease, the temperature of the body is almost always raised at least to a slight degree. This is detected by the thermometer when there is no other evidence of it, and when no constitutional symptoms are present. For the past five years I have used the thermometer in the examination of persons arriving at the New York Quarantine from infected ports, and the results have been exceedingly satisfactory. In this way many cases of infectious disease have been discovered where a visual examination indicated a normal condition of health. While there is no question as to the practical value of this test when properly employed, it becomes worse than useless if carelessly or indifferently carried out.

When thermometers are used for the purpose above referred to, they should be of the best quality and carefully tested. Furthermore, persons under observation should never be allowed to take their own temperature or report on the same. This should be personally attended to by the medical officer in charge, who is directly responsible for the examination. Care should be taken that the lips are closed while the thermometer is in the mouth, and that the instrument is not removed until the maximum period required for taking the temperature has expired. Those whose temperatures are to be taken must be cautioned not to break the thermometer with their teeth—this frequently occurs, particulary among the more ignorant class of steerage passengers, who, as a rule, do not understand the English language. In such an instance the services of an interpreter is urgently called for. It is very important that careful attention should be given to the details just referred to.

The following method employed at the New York Quarantine Station will serve to illustrate what I have already said regarding the use of the thermometer. When the temperatures of a large number of persons are to be taken on shipboard, a good-sized, well-lighted apartment is selected, which will permit the proper entrance and exit of passengers and crew. In this is placed a table sufficiently large for the material necessary for this work, *i. e.* passenger, or crew list; soap and water, bowls, and towels for cleaning thermometers, etc. At least fifty properly-tested instruments are made ready for use. These are carefully examined, to be certain that the mercury is below the normal register. Twenty-five or more persons of those who are to be examined are brought to the apartment; thermometers are carefully placed in their mouths, and the necessary instruction given by an officer of this Department, who passes up and down the line, to see that the thermometers are kept in place. When the proper time arrives, the latter are removed one by one, and the degree which the instrument registers is set opposite the name of the person examined. Those whose temperatures are sufficiently high to call for their detention are immediately conducted to the boat which is waiting to transfer them to Hoffman Island, while another group is called for. In this manner the work is continued until the entire number is examined. By having a large number of thermometers, a portion can be made ready for immediate use. Soap and water should be used for cleaning. This quickly accomplishes the desired result, and is more practical and better than dipping them in solutions of carbolic acid, etc., where they cannot remain long enough to insure disinfection. Besides this does not properly clean the instrument. Tepid, not hot, or even very warm water should be used, otherwise the thermometers may be broken, or the mercury driven to a very high degree; this may be overlooked, or it may be difficult to force it back to the normal point. The register of every thermometer should be carefully inspected *immediately* before use. If plenty of assistance is at hand, and the examination is carried out methodically, it will be surprising to see how rapidly the temperatures of four or five hundred persons can be properly taken.

In this method of examination it is necessary to know at least approximately the degree of temperature which indicates an abnormal physical condition, and which justifies us in holding persons for observation. Many thousand temperatures are annually taken at this station. In addition, surgeons of vessels coming from infected ports are requested to take the temperatures of passengers while in transit, and to report the same to this Department on arrival at Quarantine. Therefore, ample opportunity has been offered here to ascertain the variations of the normal temperature. In order to present this, I have selected a group of temperatures which were taken practically under the same conditions. The persons examined were in good health while in transit and on arrival at this port. They were of the same class of passengers (steerage), and their temperatures were taken by the same officer, and about the same time of day. In the test which I am about to present, 16,152 temperatures were taken with carefully registered Hick's thermometers, with the maximum exposure, and with careful attention paid to all details necessary to secure the correct temperatures. The results are as follows:

TABLE NO. 1.

582 were between 96 and 97° F.
1,124 were between 97 and 98° F.
2,108 were ....98° F.
779 were ....98.2° F.
7,340 were between 98.4 and 98.6° F.
2,432 were..................99° F.
976 were...............99.2° F.
811 were...............99.4° F.

While this test practically confirms the belief that the normal temperature of the human body is about 98.5° F., it also shows that considerable variation from this register may exist in the healthy subject.

In addition to the above, I have recently made the following test with some of the employees of this Department. The temperatures of eight men were taken for twelve days, at three different periods of the day; between 5 A.M. and 7 A.M.; 2 and 3 P.M., and 8 and 9 P.M. In all there were 279 temperatures registered with the following result:

TABLE NO. 2.

58 were between 96 and 97° F.
67 were between 97 and 98° F.
46 were...............98° F.
*92 were between 98 and 99° F.
11 were...............99° F.
5 were between 99 and 99.5° F.

The low temperatures found in table No. 2, as a rule, occurred during the early morning hours, between 5 and 7 A.M.—two of the eight men in this test were firemen, whose duties required them a part of the time, at least, to be exposed to a high temperature. However there was no marked difference between the temperatures of these men and others who were employed in the office. Apparently, exposure to a high temperature for a short period is not likely to raise the body temperature, as its equilibrium is maintained by sweating. However, when there is prolonged exposure, as among stokers of transatlantic steamers, etc., an elevation of temperature not uncommonly occurs. In comparing tables Nos. 1 and 2, it will be seen that by far the greater number of temperatures in both tables were between 98 and 99° F., or, more correctly speaking, about 98.5°. However, there is a marked difference in the percentages of high and low temperatures in these tables; for instance, in table No. 2, which gives the temperatures of the eight employees of this Department, about 20 per cent. are between 96 and 97° F., whereas in table No. 1 this low register (96-97) represents only about 4 per cent. of the total number (16,152). This, I believe, is readily explained by the fact that one-third of the temperatures of the employees of this department (in table No. 2) were taken very early in the morning, at which time low registers are common, while the temperatures of the steerage passengers in table No. 1 were taken, as a rule, not before 10 o'clock. On the other hand, in table No. 1, it is found that over 25 per cent. of the temperatures (4,219) were from 99 to 99.5° F., whereas in table No. 2 there is less than 5 per cent. within this register (99 to 99.5° F.). The large number of temperatures above 98.5°, found among steerage passengers referred to in table No. 1, were undoubtedly due to excitement. This factor was not present among the employees of this department concerned in table No. 2.

I believe that the foregoing tests can be regarded as reliable, and that the result shows the following important facts: (1) That the usual temperature in health is about 98.5° F., although subject to considerable temporary variation without denoting an abnormal condition; (2) That a temperature below 98° F. is much more frequent in healthy persons than is generally supposed, and that this low temperature is usually found very early in the morning; (3) That a temperature of 99° F. and above, is frequently found in the normal condition, although it is, as a rule, probably transient and due to excitement or some other temporary cause.

It is practically impossible to decide upon the degree of temperature which calls for the detention of persons coming from infected ports. When the clinical thermometer was first used at this station as a part of the examination of passengers and crews of incoming vessels, I frequently detained those whose temperatures were above 99° F., but it was soon shown that a temperature below 99.5°F. did not indicate an abnormal condition, for the reason that after the excitement of the transfer to Hoffman Island was past, the temperatures almost always dropped to 98.5° F. This elevation of temperature, 99.5° F., is very commonly found among immigrants who are sent to Hoffman Island for observation, having been passengers on vessels arriving at this port with smallpox on board. Many have also been removed with temperatures of 100° F., which quickly return to the normal register. Therefore, I believe that passengers and crews should be allowed to proceed if their temperature does not exceed 99.5°, provided there is no other reason for detention. While I am satisfied that a temperature of 100° F. by the mouth, is not inconsistent with perfect health, and is frequently temporarily found among those who are held for observation at Quarantine, or otherwise subjected to some form of excitement, I am of the opinion that this register (100° F.), should always be looked upon with suspicion.

In connection with this part of the subject, it may be of interest to state that, as the results of tests

*Almost all of these were between 98.4° and 98.6°.

made at Swinburne Island Hospital among the patients and nurses in sickness, convalescence, and in health, it was shown that the rectal temperature was usually from two-tenths to six-tenths higher than the temperature of the mouth, and that this variation occurred both in sickness and in health.

In many instances, however, the rectal and mouth temperatures were the same.

Although it is necessarily arbitrary, I believe we are justified in assuming that a temperature above 99.5° F. may indicate an abnormal condition, even in persons who otherwise are apparently perfectly well. If such a temperature is due to excitement or other temporary causes, it will not require a long detention to prove this fact, and therefore will not interfere to a serious extent with passengers and crews in transit.

X-RAYS IN THE TREATMENT OF CANCER AND OTHER MALIGNANT DISEASES.

By EMIL H. GRUBBÉ, B.S., M.D.,
CHICAGO ILL.

PROFESSOR OF RADIOGRAPHY, X-RAY THERAPEUTICS AND ELECTRO PHYSICS, ILLINOIS SCHOOL OF ELECTROTHERAPEUTICS; CHIEF RADIOGRAPHER ILLINOIS X-RAY AND ELECTROTHERAPEUTIC LABORATORY, ETC.

REALIZING that the reporting of immature results and deductions has been the bane of current medical literature, we have deferred giving for publication our experience with the *x*-rays in the treatment of malignant diseases because we wished to give the remedy the test of time. Since, however, so many articles have appeared lately upon this subject, based upon the reports of a few isolated and indefinitely stated cases with poor histories, we venture, at the risk of being accused of prematurity, to express our opinion upon the therapeutics of the *x*-ray.

This is only a preliminary report, but the writer wishes to state that the conclusions herein arrived at are not based upon cases of doubtful diagnosis, for most of them have been post-operative, and, therefore, the question of diagnosis is not an open one. We have treated with the *x*-ray, during the larger part of the past year, an average of over seventy patients each day, which we believe to be the largest number of daily *x*-ray treatments yet reported by any individual. Having had such a large number of cases to study from, and doing pioneer work in this line, we have, of course, formed some opinion of the value of the treatment; and although we do not wish to be understood as announcing this as our final opinion, owing to the fact that time may materially change it, we present what we have learned to the profession for what it may be worth.

The use of the *x*-ray as a therapeutic agent is not so new as many would suppose; in fact, several *x*-ray operators have patients now under observation who were discharged symptomatically cured by the *x*-ray more than two years ago.

At first the treatment was taken largely on faith, but now, facts, illustrating the value of the *x*-ray as a therapeutic agent, appear in nearly every issue of most medical journals, and it must be familiar to every one that an agent which can at once demand the attention of so many minds from all parts of the world, must have some merit. Have the results obtained by dozens of different writers in treating hundreds of cases all been exceptional? Have they all been spontaneous cures? Certainly not. The only logical conclusion which it is possible to form is, that there must be great value in the use of the *x*-ray for therapeutic purposes.

As a remedy for lupus, this treatment has successfully passed through the crucial test of practical experience. None who have experience will gainsay that. Since it is a fact conceded by everybody who has investigated the subject, that trophic changes, such as dermatitis, exfoliation of the skin, falling off of the hair and nails, result from exposure to *x*-rays, and since it is also a fact that lupus and epithelioma are cured, clinically at least, by the *x*-rays, why may not this agent be of value in the more malignant or deeper-seated affections?

Aside from the speculative part of the value of the *x*-ray, it certainly is perfectly logical, from every standpoint, to suppose that if we admit that tuberculosis of the skin is curable, which we must from statistics at hand, tuberculosis of the lungs or the bones, and other forms of this disease must be amenable to *x*-ray treatment, for tuberculous conditions are similar in whatever part of the body they may be found. Again, if we admit that epitheliomas are curable by the *x*-ray—and no one in the present light of things can doubt that—we can also suppose that cancer in any other part of the body is amenable to this treatment. First, because cancer tissue is primarily the same in whatever part of the body it may be found, being composed of epithelial cells; and, second, because of the ability of the *x*-ray to penetrate tissue there is no part of the body which is beyond its reach.

Many theories have been advanced as to the action of the *x*-ray in the various conditions for which it has been used. By some the belief is held that restitution of the tissues takes place under *x*-ray treatment; that is, cancer tissue becomes transformed or is developed into normal tissue. Others, taking for granted that the parasitic or bacterial theories of the origin of some of the diseases treated by the *x*-ray have been conclusively proven, believe that the *x*-ray, due to its actinic action, destroys these conditions. These theories seem rather far-fetched, however, for, aside from the lack of proof of the parasitic or bacterial origin of the diseases referred to, it does not seem probable, from observations which have been made by various investigators, that the success of the *x*-ray treatment in these diseases is exclusively due to any bactericidal power which the rays may possess.

Personally, we believe the action of the *x*-ray is the same in all the diseases in which it has been found of value, and also that that action is most plausibly explained when viewed from the standpoint of the theory of phagocytosis followed by leucocytolysis.

First, it must be admitted that, aside from whatever chemical or electric property the *x*-ray may possess, the sum total of its action is that of an irritant. Now if we irritate a certain part of the body by making frequent *x*-ray exposures, we produce ultimately a simple focal inflammation. Inflammation means the determination of much blood to the part, hyperæmia. Due to the increased volume of blood, leucocytes accumulate in large quantities and, finally, stasis occurs, the circulation being cut off, the part dies for want of nourishment. When no suitable nutritive material is at hand there is developed a tendency toward degeneration. No doubt this degeneration is partly, at least, due to an accumulation of the products of the metabolism of cells.

Primarily, then, the *x*-ray affects the essential tissue-forming elements of the body. The parts which are walled off decompose chemically and are either discharged or absorbed. The rapid decrease in the size of some growths under *x*-ray treatment also points to a more general or systemic action, probably due to stimulation of the lymphatics.

The fact that nearly every case, no matter how severe, treated by the *x*-ray seems to improve at the beginning of the treatment, shows that it exerts an influence which is not only local but also systemic. From our personal observations upon several hundred patients we have come to the conclusion that the nutrition of the entire system is affected, through reflex action probably, and this produces a general stimulating and tonic effect. As to the special characteristics of the *x*-ray in different conditions our experience teaches that the vitality of all patients is increased. It is surprising how long life may be maintained in some cases. Relief from pain is found in the majority of cases, although if a neuritis is coexistent with cancer, especially in breast cases, very little can be done for the relief of the pain.

Tuberculous conditions, especially lupus vulgaris, have been most favorably affected by the *x*-ray. In our own use of this agent the following is the relative order in which we should classify the diseases for which the *x*-ray treatment has been given, and the order in which we should expect results, relatively: lupus, epithelioma, nodular returns (post-operative), primary breast cases, tuberculosis of the lungs, tuberculosis of the bones, cancers of soft internal organs, sarcomas, osteosarcomas.

In making this classification we do not wish to assert that all the above-named conditions have positively been cured by *x*-ray treatment. Statistics to that effect are not yet at hand. We are not optimistic enough to assert that all cancers can be permanently arrested or cured by this or any other known method of treatment, but we do believe that the *x*-ray has established for itself a field in the therapeutics of lupus and epithelioma. Not only that, but the future will see its greatest application in the treatment of patients immediately after operation, to prevent the possibility of recurrence.

Without in any way wishing to depreciate the splendid work of surgery, we must say that recurrences are only too numerous. It is a well-known fact that in only a small percentage of the cases of cancer operated upon does the growth fail to return. Concerning the status of the value of the surgical treatment of carcinoma, we quote from an editorial in the Medical Record of April 5, 1902, in which it is said that "we know our limitations in the radical surgery of carcinomatous diseases, and we recognize the fact that our best efforts do not cure, but only in a small proportion of cases annihilate the neoplasm."

It is not recommended that the *x*-ray take the place of the knife in primary or operable malignant growths, but the results so far obtained by *x*-ray treatment following operation are certainly sufficient to warrant the careful consideration of the profession. In general, the results of *x*-ray treatment speak for themselves, and it is unnecessary to present here any argument concerning the practicability of the use of this agent. Enough has already appeared upon this in medical literature.

It may be well, however, to point out that the whole matter resolves itself into the question of a proper understanding of *x*-ray phenomena. It is the correct use of this agent for special conditions, with ability to vary its power when necessary, that is essential for obtaining proper results, and not its use in the haphazard manner which is so common to-day, when, through ignorance of its virtues, the *x*-ray, which is hailed as a triumph by the physician in his struggle against tuberculous and cancerous conditions, becomes a dangerous force in the hands of the incompetent operator. We must not forget that we have a great variety of *x*-rays to deal with—in fact, to use a comparison, the variation in quantity and quality of *x*-rays obtainable with one piece of apparatus is much greater than all the varieties and qualities of tones which may be produced upon the keyboard of a piano. Again, different tissues demand different degrees of *x*-ray value.

When we understand these facts we can readily see why the treatment of an epithelioma must be different from the treatment of lupus. Ignorance of these facts probably accounts for much of the difference of opinion which exists to-day regarding the therapeutic value of the *x*-ray.

A few words concerning the so-called *x*-ray "burns." The continued administration of the *x*-ray in any one locality produces, at first, through its irritating influence, a dermatitis. If the treatments are unduly continued, ulceration of the tissues may occur, but an *x*-ray "burn" need never be considered serious. This statement is made because of the many bold announcements which have appeared concerning the "dangers of burning under *x*-ray exposure." Relatively, the inflammatory reaction, or dermatitis, produced by the *x*-ray is harmless, and, in most cases, if the parts were not meddled with by the application of strong chemicals, especially carbolic acid in some form or other (which, of itself, may cause gangrene), nature would assert her power and make repairs. We believe we have "burned" every patient treated, and several of them have been "burned" repeatedly. Concerning the development of the dermatitis, we find that susceptibility varies considerably. Certain individuals develop a decided reaction after the first treatment, whereas others resist the action of the rays to such a degree that it is only after from one to two months of daily treatment that we are able to develop a reaction. In one case daily treatments have been given for over two years, and, although the tube has been placed very near the body, nothing more than a slight redness has developed. It is evident from this that an idiosyncracy must exist.

To prevent the action of the rays upon surrounding tissues, a special lead-foil mask is used, which resists the passage of rays to healthy parts. Another precaution might be recommended, in order that the "burning" stage may be retarded—it is the application of plain vaselin to the parts exposed directly to the rays. This substance retards the superficial irritation very much, and is especially useful when treating the deeper tissues, and when there is no open ulcer. In all open or broken-down conditions a dermatitis should be rapidly produced.

The following are brief reports of a few cases:

Case 1.—Mrs. M., aged forty years, recurrent carcinoma of right breast. Radically operated upon first time in August, 1900. Recurrence immediately, followed by second operation. Six months after second operation nodules again began to appear in scar tissue, and third operation was performed. After this the nodules remained away for nearly one year, but finally they appeared again, and the patient undertook *x*-ray treatment. The whole scarred area was filled with a large number of small nodules, each about the size of a pea, which extended even into the axilla. Under *x*-ray treatment these nodules gradually began to fade away. The patient's appetite improved, pains disappeared, and she felt stronger, and was visibly improved in general health, so much so that her friends constantly inform her of her improvement. In this case the treatment was not taken as regularly as recommended. Sittings were given daily for about one month, and on alternate days for nearly four months. Although we do not consider this patient absolutely cured, she certainly shows so much improvement that we think we are justified in calling this a symptomatic or clinical cure.

Case II.—Mrs. L., aged forty-eight years, case of scirrhous cancer of right breast. Three years ago last January a small hard tumor was noticed, which was painful to the touch. Her physician suspected a malignant condition on account of the family history, and an operation was performed, the breast being moved. Last August three nodules began to develop simultaneously in the operation scars. These nodules grew quite rapidly, and since another operation was refused, patient was recommended by her surgeon to try *x*-ray treatment, which was accordingly begun on September 5, last. Treatment was given daily until November 15, when decided dermatitis developed. The patient was allowed to rest until December 5, when treatments were begun once more, and continued daily until January 20, at which time all three of the nodules had entirely disappeared. This case also presented a condition of keloid, which extended over an area of six inches, and which also was very markedly affected by the *x*-ray exposures.

Case III.—Mrs. O., aged fifty-six years, cancer left breast—so diagnosed by several prominent physicians who had treated her. The original growth presented an ulcerated surface measuring seven by five and one-half by two inches. Several severe hemorrhages had taken place, and patient was very weak. Discharge foul and very profuse. Glands in axilla swollen and very tender. Pain in growth and surrounding parts constant and, at times, excruciating. Many methods of treatment had been tried during a period of nearly three years, but were found to be of no value, the condition gradually getting worse. Finally, *x*-ray treatment was advised and undertaken. Treatment given every other day for twenty minutes. No improvement or effect was noticed, other than relief from pain, until after the third week of treatment, when decided dermatitis had developed and pains again returned, due to dermatitis. Treatment, however, was continued every other day, tube being placed farther away from affected area, and in about two weeks more a marked change was noticeable. The hollow cavity of the growth seemed to fill in, the edges of the ulcer began to approach one another, and in three months from the beginning of the treatment the wound had healed over entirely, and the patient presented the appearance of having been born with only one breast, so slight was the scar. This patient has been under observation for nearly one year, and during this time no recurrence has been noticed. Patient is a very active woman, and travels extensively.

Case IV.—Mrs. A., aged sixty-five years, case of lupus involving entire forehead, left temporal region, left cheek and eye, and extending to the middle of the left side of the nose. The most extensive lupus formation we have ever seen. Primary lesion a pimple, which developed on left cheek bone over fifteen years ago, constantly grew larger until thirteen years ago medical aid was sought. Various local preparations were tried without avail. Lupus area became constantly larger, even though patient has been practically under treatment of some kind or other for the past thirteen years. Two years ago plaster treatment was resorted to without any beneficial result, and since then the growth discharged constantly and itched intensely, and patient became very weak, due to constant irritation. *X*-ray treatment began December 2, 1901, and continued every day until January 10, 1902, at which time the looked-for dermatitis had developed over the entire area, and the patient was allowed to rest from treatment. Three weeks elapsed before the irritation had run its course, and, at that time, all parts were covered with new and healthy skin. A month later the hair again began growing, on head, eyebrows, and eyelashes, and not a vestige of the old trouble can be found.

Case V.—Mr. P., aged fifty-five years, lupus on left cheek, surface size of twenty-five-cent piece. Ten years ago patient noticed small festering pimple on cheek, which was opened by scratching with the finger nail. This has never healed over in spite of the fact that he has been constantly under treatment, and tried, among other things, the actual cautery three times, excision once, and plaster treatment five times. Patient was sent to us by his son, a physician, and *x*-ray treatment recommended. Treatment given daily for seven weeks, at which time considerable dermatitis had developed, and patient was allowed to go home, and instructed to return as soon as the irritation, due to the treatment, had subsided. The dermatitis did not subside for nearly three weeks, when patient appeared, and we found a small area in the center of the old formation, which needed treatment. Accordingly, treatments were again given daily for two weeks, when dermatitis once more developed, and patient was again allowed to rest from treatment. On returning two weeks later we were unable to find any trace of the previous trouble, and since that time, now nearly six months, we have seen and examined this patient several times, and have been unable to find any return of the lupus.

Case VI.—Mrs. F., aged fifty years, large scirrhus on left breast of three years' standing. Had injection treatment without any favorable effect. Would not undergo surgical treatment because she had heard of many recurrences following operation. *X*-ray treatment undertaken April 15, 1901, daily for first two months, after which decided dermatitis developed, and the breast began to break down, and discharged not only a large quantity of fluid, but also much solid cancer tissue. This breaking-down process continued for over one month when the parts began to heal. The growth seemed to have been entirely enucleated. Treatments were now given every other day, and in the course of two months or more the wound had entirely healed, and, indeed, without much scarring. This patient has been examined frequently, and no return detected.

Case VII.—Mrs. E., aged fifty-two years. Early in the year 1900 the patient complained of pain in the pelvic region. On consulting several physicians the diagnosis of cancer of the uterus was made and operation was recommended. Operation for removal of entire uterus was performed March, 1900. Following this operation, a persistent discharge was noticed. The patient took a severe cold in the month of December, 1900, and symptoms of congestion appeared in the pelvic region, followed by the development of an abscess, which broke and discharged through the vagina. Discharge continued offensive, with occasional very profuse hemorrhages. A second operation was recommended and performed by a prominent surgeon in May, 1901. On making an incision the surgeon found that the cancer had returned, and was so extensive in character that he decided not to remove anything. The wound was closed, and the husband was told that nothing could be done to save his wife's life, and that she would probably die within a month. During the last week of May, 1901, patient was brought to Chicago, and *x*-ray treatment was undertaken. Daily treatment of ten minutes' duration were given, and at the end of two months the patient had gained twenty-two pounds, was free from pain, and the foul discharge had almost entirely ceased. At the end of three months she was discharged symptomatically cured, and she remains so to this writing. During the past eleven months she has gained thirty-five pounds, and writes "I continue to keep well; have not felt so well in years."

We have a number of other patients who have taken *x*-ray treatment, and who have remained free from recurrence for periods ranging from six months to a year and a half. Many other cases could be cited, but time and space forbid.

In conclusion, we wish to submit the following deductions:

1. The *x*-ray is the most remarkable therapeutic agent of the last decade.
2. In properly selected cases of so-called "incurable conditions" the *x*-ray has brought about remarkable results.
3. Relief from pain is one of the most prominent features of the treatment.
4. Retrogressive changes are noticed in all primary cancer or tuberculous growths.
5. The *x*-ray has a pronounced effect upon internal cancers.
6. The greatest value of the *x*-ray is obtained in treating post-operative cases to prevent recurrences.
7. The proportion of clinical cures by this treatment is greater than that obtainable by any other method of treatment.
8. We are positively justified in assuming an idiosyncrasy to *x*-rays.
9. The peculiarities of each case must be studied in order to get the best results, *i. e.* no strict rules for treatment can be laid down.
10. Dermatitis, if properly produced, is within certain limits a desirable feature of *x*-ray treatment.
11. Since the vacuum of an ordinary *x*-ray tube changes constantly, such tubes are useless for radiotherapeutic work, and only tubes which allow of perfect control of vacuum should be used.
12. The *x*-ray has a selective influence upon cells of the body; abnormal cells being effected more readily than the normal.
13. Hemorrhages and discharges are decidedly lessened and, ultimately, cease in the majority of cases.
14. Even in the hopeless, inoperable cases, the *x*-ray prolongs life, makes the patient comfortable, and the last hours free from pain.

The use of the *x*-ray is, without doubt, a very valuable addition to the therapeutics of malignant diseases, and cannot demand too much attention from the progressive physician.

Whatever may be the real action of the *x*-ray in these diseases, the results obtained certainly have been astonishing, and while it would be premature to claim that malignant diseases can positively be cured, it is to be hoped that further investigations may surpass our expectations.

126 STATE STREET.

An Early Sign of Pleural Exudation.—Przewalski has noted in very early stages of pleural effusion a narrowing of the intercostal spaces and a marked resistance of the intercostal muscles of the affected side. This seems to be analogous to the muscular contraction observed in a limb in cases of arthritis. He regards this as a constant and typical sign of pleural effusion, and considers it due to a fixed attitude of the rib corresponding to the seat of the disease, the immobility being due to reflex contraction of the internal intercostal muscles.—*Medical Times and Hospital Gazette.*

HYDRÆMIA AND MALARIA

By R. CADWALLADER, M.D.,
WINTERS, CAL.

The town of Winters, Cal., has an unenviable reputation for malaria. It is on the north bank of a stream which, while running the summer through, diminishes to less than a foot in depth before the winter rains swell its thirty-foot banks nearly to overflowing. This stream has very few back-water eddys, none of which are undrained, and is filled with small fish. Mosquitos of the Anopheles variety exist in not great numbers, but sufficient to be annoying to those who want to follow a local custom and sleep out of doors during the hot nights.

One street runs parallel to this stream, the lots going back to the bank, and I wish to call attention to the cases of malaria found in the houses on that side for some four blocks.

First house—Three adults and one boy of twelve. The father, a hard-working blacksmith, had one mild attack; the others had several each. A daughter, aged twenty-four, had three severe attacks. Earlier in the summer, for constipation, I had advised her to drink water freely.

Second house—Two adults. Both had mild attacks. They had worked hard all summer.

Third house—Father, mother, and four children. The family, except the husband, were away all the summer, but returned September 1. The mother and one child took sick September 17 and 23. The father drank only bottled water at meals and escaped.

Fourth house—Man over eighty years—free.

Fifth house—Old man and wife—free.

Sixth house—Father and son. I had advised the father to drink water freely because of urinary sediment, in July. He had a severe attack in August and another in September.

Seventh house—Four persons absent during most of the summer, except the father, who was a small eater and drinker, because of dyspepsia.

Eighth house—Three adults. Father dyspeptic; young man, absent all summer. The mother I had advised to drink freely of water, and during the summer she had two severe attacks.

Ninth house—Old couple, who were advised, in July, to drink plenty of water, as in both cases the urine was loaded with salts. Both had severe cases of malaria in August.

Tenth house—Four adults. Wife and daughter had mild attacks each.

Eleventh house—Two adults. Wife had a mild touch early in the summer; but, at the close of the summer's work, and after being advised by me to "flush out," the husband was taken with one of the most troublesome cases I have had this year.

Twelfth house—Three adults. Two of these were advised to drink water for constipation, and these two were sick in July.

Now, opposite these four blocks, I had, in one family of seven, two cases, and to both of these I had advised water. In a second, water was advised to the wife, who had a severe attack two weeks later. The husband drank only at meals, and has been free.

This street is well shaded, is eighty feet wide, and the prevailing wind is toward the creek, which accounts for the great number of cases on that side. I might add that there were only three families that escaped entirely, and that four more had malaria, but were under the care of a brother practitioner.

In thinking of these cases, I was struck with the fact that on the north side I had only three cases, and to these three, out of the other members of the families, I remembered to have prescribed the free use of water. I then looked over the cases noted above. Here are thirty-five persons, of whom nineteen had malaria this season. To eight of the nineteen I had advised water in large quantity, and, it is worthy of notice, that, with one exception, these eight had been my most severe cases.

Thinking that this might be a coincidence merely, I ran over my cases for August and the first half of September, and selected those at least two miles from town, twenty-five in all. Four of these had been advised to "flush out"; two followed within two weeks of a changed water supply, the old being impure and hardly fit to drink; two had started to school after a summer's work, and the others, excepting two, had finished the fruit season of hard, perspiring, outdoor work from one to two weeks before and were "resting up." In each case there was a history of increased amount of water taken in or lessened excretion. This, then, was the same condition that was found in the patients of the four city blocks.

In connection with this it is worthy of note that the fruit season, *i.e.* the time of hardest work and hottest weather as well, ended with August, and was followed by cooler weather, without rain, during the first ten days of September. This change was marked enough to make blankets at night necessary; and as the elimination of water by the skin was decreased, the hydræmia was, of course, increased, and this was also the very time when I had the greatest number of cases.

There is a firm belief in this locality that eating watermelons will cause "the chills." Forgetting the fact that back of these popular fancies there is often a truth, I was inclined, a year ago, to consider a coincidence merely in the time of ripening. In considering the deductions from these cases and the etiology of malaria, it has occurred to me that perhaps an increased proportion of water in the blood to the normal may play a very important part in the causation of malaria. To do this, it must either render the system more susceptible to the infection, make the effects more severe when once the body is infected, or favor the flow of saliva from the mosquito to the subject. The season is too far advanced and the material too limited for me to prove this theory at present, but it fits in with one other observation that I have never heard or read. This is the lack of thirst in the fever of malaria. A temperature of 103 or 104° is not followed by demands for water, when in fever from any other cause patients will want to drink continuously. If it be proven that hydræmia is a predisposing, and it may be an indispensable, prerequisite to infection, then the drenching sweats are probably Nature's way of reducing the fluids of the body to a point causing the death of the plasmodium. It has been said that the pyrexia is the cause of death to the germ, but this is hardly possible, for at its height the plasmodium can be found in abundant numbers.

I called attention to dyspepsia in houses 7 and 8 because it was atonic in character, and the patients have been unable to eat or drink much at a time.

This theory furnishes a reason why the disease is more prevalent with colder weather in the fall at a time when the mosquito is sluggish and is found in fewer numbers, and when in this locality the habit of sleeping on lawns has been given up. It has been noted that "in malarious regions the number of cases is usually materially greater during a summer attended with a heavy rainfall than during a dry summer. In tropical countries the first notable increase in the number of cases occurs when the dry season is first terminated by the autumn rains, but when the rainy season has continued a sufficient length of time to more or less completely inundate the surface of the ground, a decrease in the prevalence of the disease takes place. When, however, upon the termination of the wet season the sun regains its full vigor, the evaporation of the moisture from the ground that ensues causes the number of cases again to be largely augmented." (Mannaburg, in Sajous' Cyclopædia.) Or, in other words, the cases of malaria exactly follow inversely the water excretion of the people, which may be taken as a fair index of the hydræmia of their blood.

Quinine is the one specific drug for this disease, and, besides a germicidal action, it has the marked effect of increasing vasomotor constriction, as Sollman says, "a quickened pulse with rise of blood pressure." This greater blood pressure increases the amount of urine excreted therefor, and lessens the water in the body. Now, consider the substitutes for quinine. Except for arsenic, which relaxes the capillaries, but, while doing this, acts energetically on the intestinal canal, producing watery movements, they are all diuretics. In this list are methylene blue, strychnia, nitrate of potassium, iodide of potassium, myrrh, eucalyptus, lemon juice, guaiacol, and phenocol, pepper, etc., every one of which have diuresis as their principle, if not only, action. While they are poor substitutes for quinine, the fact that diuresis is their only common action is a strong presumption that that is the line of their beneficial action. It is also well known that brisk purgation by mercury, while taking quinine, wonderfully assists in the cure. In his work on estivo-autumnal malaria, Craig states that "of returned soldiers from the Philippine Islands, 65 per cent., showing estivo-autumnal parasites in the blood, were suffering from acute or chronic dysentery." This does not seem to me, as at first might be thought, the tissues being thereby drained, to disprove my theory. It is the effect of the economy to deplete the body to a point of killing the germ, though often in those severe cases an unsuccessful one. Almost in the next lines we find him stating "that the administration of quinine in cases of estivo-autumnal malaria, complicated by dysentery, not only removes the malarial infection, but, in many instances, the dysentery improves, and a return to health is more rapid." His explanation of this is that the intestinal membrane is invaded by the parasite causing an irritation, and hence the diarrhœa; but it would seem equally plausible to consider it also as an effort to get rid of all the water possible. And not without significance, also, are his statements that "during the paroxysms the amount of urine passed is increased," and that in "tertian and quartan fevers convalescence is often marked by the occurrence of polyuria," and that "a slight polyuria is very common, and is probably more so than is generally known," and also, "that, on the whole, there is little variation from normal in the specific gravity of the urine."

He also calls attention to how infrequently typhoid and malaria coexist, quoting Dr. Lyon's list of only twenty-nine authentic cases, and giving but five as his own experience. He says, "As a rule, the malarial attacks occur during convalescence from typhoid;" namely, after the characteristic diarrhœa of the disease is over.

It may be that this theory is incorrect. A few cases in one locality prove nothing, though it does seem to fit in nicely with the known facts of malaria. If it be proven correct, then we have an interpretation of how and why certain drugs act as they do, and surely gives us a hint toward prevention as well.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, November 1, 1902.

THE OPERATIVE TREATMENT OF EXOPHTHALMIC GOITER.

THE name of Kocher has long been associated with the treatment of all forms of goiter, and the bearer of that name has had unequaled opportunities for observing the disease in all its forms. Any contributions, therefore, coming from the Berne clinic must have unusual interest. In a paper in *Mittheilungen aus den Grenzgebieten der Medicin und Chirurgie*, Band IX, A. Kocher, a son of the well-known surgeon, offers a paper containing the results of treatment in ninety-three cases of exophthalmic goiter, occurring during the period between 1883 and 1899, and coming under the charge of the elder Kocher. Among these cases seventy-four are said to have been examples of true exophthalmic goiter, fifty-nine of which were subjected to operation. It is hardly necessary to mention that cases of exophthalmic goiter belong in a special category, and cannot be judged by the same standards which we use in the case of other forms of thyroid enlargement in which we do not have a serious constitutional derangement to contend with, and for which we can recommend operative treatment with considerable assurance.

Kocher exercises a careful selection of cases for operation, and does not permit patients who are evidently in an exacerbation of the disease to be operated upon until an attempt to mitigate this condition has been made by whatever form of medicinal, hygienic, and dietetic treatment seems to hold out the greatest prospect of success. In this series of cases it is interesting to note that all operations were done under local anæsthesia with a 1 per cent. cocaine solution. The nature of the operation varied from excision of one lobe of the thyroid gland to ligature of the thyroid arteries. In three cases we may note that the arteries were tied, and at the same time that the cervical sympathetic was resected.

Among these fifty-nine cases operated upon there were four deaths within ten days of operation from what was apparently well-marked tetany, and in thirty-nine other cases there were well-marked constitutional disturbances, most of which could not be considered as merely usual after a considerable surgical operation. Many of the symptoms were clearly referable to the sympathetic system, such as tremor, palpitation and irregular cardiac action, sweating, vomiting, and, in a few cases, a transitory increase in the symptoms observed before operation. It was noted that in all of these thirty-nine cases operation was followed by a more or less protracted elevation of temperature, and by rapid heart action. This circumstance suggests that some of the symptoms, at least, of exophthalmic goiter depend upon the circulation in the blood of a toxic substance, the presence of which is occasioned by the faulty or perverted metabolism of the thyroid gland, and that during operation an unusual amount of this is forced into the blood-current. According to Kocher, this view of the matter is looked upon more as a possibility than as a probability, but further observation may lead us to a more definite conclusion.

The ultimate results in this long series seem to have been very good, since among the fifty-nine cases operated upon cure is said to have resulted in forty-five, and marked improvement in eight others. When we compare these figures, which have undoubtedly been very carefully considered before being given out, with the results reported to have been obtained by medicinal treatment, the superiority of the operative method is evident.

There is a class of cases of thyroid enlargement in which the chief feature is a great increase in the size and the number of the blood vessels, with a consequent increase in the size of the gland itself. The disease is not true exophthalmic goiter, though in many instances there is a close resemblance. In Kocher's series, nine such cases were subjected to the operation of ligature of the thyroid arteries, in all with exceedingly satisfactory results. Cases of this kind must be kept in mind, and it must be remembered that they are much more amenable to treatment than are cases of the true exophthalmic variety. It was possible in three of the fatal cases to obtain autopsies, but the findings did not show any cause of death which could be referred to the operation, and there were no uniform pathological appearances. Our knowledge of exophthalmic goiter is still unsatisfactory, and our best treatment is empirical when it is not operative. With many of the symptoms we can cope, but why the symptoms should be present we do not know, except in the case of those which are dependent upon the pressure of the enlarged organ in the neck. Why exophthalmas should be very marked in some cases and very slight in others, as, indeed, why it should ever occur, we do not know. There is a vicious circle in the disease, but which of its elements is the primary offender we cannot at present affirm. Our experience, confirmed by every new series of cases reported, is that by a judicious operation we relieve the patient of one of the most important elements in his disease, and in many cases make it possible to overcome the rest by appropriate treatment. It is still a matter of doubt whether the removal of the thyroid enlargement is beneficial because a source of mechanical pressure is removed, or because a secreting organ whose metabolism is so changed that its product is toxic is thus prevented from any longer sending this product into the blood current. Certain of the symptoms of exophthalmic goiter seem without doubt to depend upon some form of toxæmia.

This series of Kocher's is interesting because it is so large, and because it comes, as we have said, from a clinic where so much has been done with diseases of the thyroid. The results intrench the surgeon behind his dictum that the proper treatment of exophthalmic goiter is first operative, and second medicinal and hygienic.

HUMAN AND BOVINE TUBERCULOSIS.

Ever since Dr. Koch gave expression to his views on the intercommunicability of human and bovine tuberculosis, scientists in all parts of the world have been delving into the question. The majority of these have declared that Koch had not sufficient basis from which to launch an argument so destructive of existing beliefs, and that, consequently, he was ill advised to propagate a theory which might do an infinite amount of harm.

At the Sanitary Congress, held a short time ago in Manchester, Eng., Professor Edward Nocard of the Veterinary College, Alfort, Paris, vigorously antagonized the opinions advanced by the German scientist. Professor Nocard is one of the foremost veterinary surgeons in the world, and is especially distinguished for his knowledge of the scientific branches of his profession.

Professor Nocard, in the paper he read at Manchester, said, in part, Koch's communication resolved itself into these two declarations: (1) Bovines are refractory to human tuberculosis; (2) All measures taken to protect man from bovine tuberculosis are unnecessary. He then proceeds to dissect these propositions as follows: "(1) It was already known that it was both difficult and rare to communicate human tuberculosis to healthy bovines; attempts to inoculate almost always fail; but occasionally they succeed, and in these cases the lesions caused are absolutely analogous to those of the natural disease. The facts recently published by Thomassen, Ravenel, Prettner, Arlaing, Spronck, Max Wolff, myself, and others, entirely conform to the old experiments of Chauveau, Kitt, Bollinger, Crookshank, Sidney Martin, Fotheringham, Smith, and Dinwiddie, therefore the first proposition of Koch's is erroneous; the bovine race is not refractory to human tuberculosis. (2) But admitting, for an instant, the truth of this proposition, would this oblige us to conclude that man is not susceptible to bovine tuberculosis? No, a hundred times no. All comparative experiments in every country prove that the bacillus of bovine tuberculosis is far more virulent for all species of animals than the bacillus of human origin. No matter what the process of infection adopted, no matter what the species of animal experimented on, the bovine bacillus kills more quickly and more surely than does the human bacillus. Why should the human species alone prove an exception to the rule? It is difficult to experiment upon men, but there are recorded numerous scientific observations which prove the possibility of inoculating man with bovine tuberculosis. Most of these cases relate to veterinarians or butchers, who, in the course of autopsies of tuberculous cattle, have wounded themselves. Such wounds have generally developed tuberculous lesions, which usually have been cured by a slight operation, but occasionally such lesions have generalized themselves and to so great an extent as to cause the death of the victim."

The history of two cases of this nature which resulted fatally is then given, and Professor Nocard asserts "Koch is no more accurate in his second proposition than in his first. Tuberculous bovines can give tuberculosis to man." The French professor ends his paper by declaring that experiments confirm the results arrived at by observation. With all mammalia the ingestion of large quantities of milk from cows with tuberculous udders speedily provokes tuberculosis of the intestines, the peritoneum, and the mesenteric ganglia. All mammalia, including monkeys, become tuberculous after ingestion of milk from tuberculous cows. It would be absurd to contend that man alone offers an exception to the rule.

The array of well-known authorities who hold that bovine consumption can be communicated to man, and that the ingestion of milk from cows with tuberculous udders may convey tuberculosis to those who drink it, should be sufficient to warn the public that there is danger from this source, which needs to be carefully guarded against.

PARASITOLOGY OF ACUTE ARTICULAR RHEUMATISM.

Evidence is rapidly accumulating to show that acute articular rheumatism is a disease of bacterial origin. Many facts in its clinical course, its complications, and its therapeutics, point to this conclusion, but the crucial test of isolating the specific microorganism and producing the disease experimentally by inoculation with cultures of the same has hitherto failed. Fritz Meyer has, however, recently made some investigations (*Zeitschrift fur klinische Medicin*, Vol. 46, Nos. 5 and 6, 1902) which have the promise of most important results.

In a first series of studies he cultivated the blood and inflammatory exudate of the joints from more than thirty cases of acute articular rheumatism with absolutely negative results, never being able to demonstrate the presence of microorganisms therein. Starting anew from the assumption that, in this disease, the tonsils are the portal of entry of the infection, twenty-six cases of tonsillar angina, all of which immediately preceded an attack of acute articular rheumatism, were examined bacteriologically. Portions of the tonsils were excised and cultivated for twenty-four hours in peptone or ascites bouillon. This bouillon was then inoculated intravenously into rabbits. The rabbits thus inoculated regularly developed symptoms of acute articular rheumatism which were practically identical with those observed in the human subject. Of 100 animals inoculated, twenty-one showed, at autopsy, lesions of endocarditis. From the inflammatory joint exudate of these rabbits, and from the endocardial excrescences (in those animals in which endocarditis was present), there was isolated a peculiar streptococcus which was identical in morphology and cultural characteristics with a streptococcus present in the original tonsils examined. This microorganism was, however, obtained from the joint exudate only when such was examined very soon after the initial appearance of the symptoms. In all of the animals in which the examination was delayed the exudate proved to be sterile.

Morphologically, these organisms appeared in short chains of diplococci. They did not, however, show the lancet-shaped forms so characteristic of the pneumococcus. When taken directly from the tissues the chains were much shorter than after cultivation upon artificial media. They stained readily with the ordinary aniline dyes. With Gram they took a lighter blue than the ordinary species of streptococci. They grow most abundantly in 2 to 3 per cent. peptone bouillon, to which a little human blood serum or ascites fluid had been added. They grew better anaerobically than aerobically, especially if 1 to 1½ per cent. of glucose was added to the culture media. They grew abundantly upon ordinary agar, but only poorly upon potato. Upon all media their growth was of very short duration, the cultures dying after four or five days, their virulence, however, did not seem to be altered up to the time death occurred. Although their inoculation with rabbits regularly produced the symtoms of acute articular rheumatism, as above stated, the death of the animal did not result therefrom unless an endocarditis developed. Repeated animal transference did not seem to increase the virulence of these microorganisms. The examination of the endocardial excrescences in the cases in which endocarditis appeared showed that the microorganisms were inclosed in these inflammatory masses, so that the latter were, apparently, sterile unless they were broken up previous to cultivation. For this reason it was found that the organisms were much more easily obtained from these growths in recent than in chronic cases. In none of the animals was any infection of the various bodily organs present, nor did any necrosis of the tissues seem to be present as the result of the microbic infection. Control experiments were conducted in which animals (rabbits) were inoculated with a variety of other bacteria (B. typhosus, pneumococcus, ordinary streptococcus, staphylococcus, etc.), but in no instance were lesions, in any way similar to the above, produced. Rabbits were also inoculated with mixed cultures of these other bacteria and the special microorganism here described. In all of these cases the latter was obtained from the articular lesions produced, but the other bacteria could never be found in this location.

From all of these facts it is apparent that this special variety of streptococcus has a marked affinity for the joints, and localizes itself in them whenever it is introduced into the animal body, and that in this location it produces an inflammation known as acute articular rheumatism. The microorganism could not be obtained from the blood, and only from the inflammatory joint exudate when this was examined early in the disease. Its simultaneous presence in the tonsils would appear to show that these organs are the portal of entry of the infection.

The Berlin Congress on Tuberculosis.

The medical journals of every country have discussed consumption in all its aspects almost *ad nauseam*. The persistent harping upon the same subject, however, has had the effect of arousing the attention and interest of the general public, and of loosening the pursestrings of the rich. It may be safely said that more has been effected within the past ten years to save consumptives and to abolish tuberculosis than in the hundred preceding years. On October 23 the International Congress for the Prevention of Consumption opened at Berlin. There were present leading authorities on the disease from all the foremost countries of the world. France was represented by no less than twenty delegates. The papers read were all of a practical nature, and demonstrated the remarkable progress which has been made in successfully fighting tuberculosis. Professor von Leyden has initiated a system of sanatoria for the working classes, and, in accordance with this scheme, large public sanatoria have been built in the pine forests, in the vicinity of Berlin. These institutions are run in connection with the workmen's insurance fund, and provide every accommodation for the victims of consumption, as well as of the various forms of kidney affections. The sanatoria are built on the cottage plan and, of course, the part devoted to the care of consumptives is isolated from that in which sufferers from kidney complaints are housed.

Professor Brouardel sketched the advance made by France in the sanatorium treatment of consumption, and said that France now has twenty-five sanatoria, and that, owing to public and private generosity, many special establishments would be erected.

Mr. Hillier, speaking as the mouthpiece of the British association, submitted four measures for the prevention of the spread of tuberculosis. First, the prohibition of expectoration under penalties; second, systematic notification of phthisis; third, efficient ventilation and lighting in all factories and public and private buildings, and, fourth, the establishment of sanatoria for tuberculous cases in early and advanced stages, and for the treatment of phthisical cases.

The Congress at Berlin has been the means of bringing prominently into evidence the system introduced by Professor von Leyden for the benefit of working people suffering from tuberculosis. Persons of this class are the most difficult to treat with much hope of permanent relief. They are unable to enter sanatoria at their own expense, and are thus not only compelled to lead a life of misery and suffering, but are the chief factors in spreading the infection. It would be to the advantage of all—rich and poor alike—if the German professor's system were adopted everywhere.

It is stated that the delegates to the Berlin Congress were greatly impressed with the successful working of the sanatoria conducted on Dr. von Leyden's plan, and would recommend that institutions of a similar kind be established in their own countries.

Professor Koch recapitulated and adhered to all that he said with regard to the non-communicability of bovine tuberculosis to man, at the Congress held in London last year. He defended stoutly the position he had taken against his numerous critics, and questioned the statement made by many English medical men, that contaminated milk is a frequent cause of intestinal tuberculosis among children. His remarks at the Berlin Congress will doubtless raise another storm of discussion on this much-disputed matter

---

The Strenuous College Football.

The football war is once more waging, and several of the battles have been hard fought and bitter. Many casualties have already happened. Two or three men have been killed and several others have been more or less severely injured. In a match played between Princeton and Columbia Universities on October 26, the contest was especially fierce, and marked by some rather serious mishaps. One man had his collar-bone broken and his trainer declared that it was the worst fracture of this kind he had ever seen, and that he would not allow him to play again during this season. Another man was compelled to retire with a similar injury, while yet another was hurt.

In a game—so-called—which took place at Baltimore on the same day, the proceedings were enlivened by a free fight between some members of the respective teams. Police interference prevented an amusing interlude from developing into a Donnybrook Fair on a small scale.

The Medical Record, on several occasions, has protested against the unnecessary brutality of college football as at present played. The term game is scarcely applicable to up-to-date football. Not only does a proper knowledge of its intricacies require an undue proportion of a student's time, causing him to neglect studies which are to fit him for his career in life but in addition he runs the risk of being seriously maimed.

There is no reason why American football should have gained so unenviable a notoriety as a distinctly dangerous game. In Great Britain the game is even more popular than here, but is free, to a great extent, from the objectionally rough tactics which mark it in this country. It would be well, and in the best interests of both students and parents, if the rules governing American college football underwent a radical reform.

The Dust Problem.

At the Sanitary Congress recently held in Manchester, England, among other important matters relating to sanitation which were discussed, the question of how to effectively deal with superfluous and harmful dust occupied a prominent position.

Sir J. Crichton-Browne—the orator of the medical profession in Great Britain—delivered an address, as President of one of the sections, and took dust as his text. He said, in part, that industrial dust, apart from poisonous or pestilential mixture, was a sufficiently interesting theme from a sanitary point of view, for the returns of mortality revealed that, notwithstanding the highly successful crusades against it, it was still responsible for an appalling amount of suffering, disablement, and death. A detailed examination of the condition of work in each of the twenty-two principal dusty trades brought out clearly that it was the dust that was primarily at fault in causing their unhealthiness, for there was always a relation between the death rate and the quantity and quality of the dust present. There could be no doubt that it was ganister dust that was responsible for the alarming mortality amongst those who worked in mines, brought to light by Dr. Birmingham and Dr. Robert Shaw, and that it killed, not by inducing phthisis in the ordinary sense of the term, although that was the commonly certified cause of death, but by setting up a more or less widespread fibrosis in the lungs, to which tuberculous phthisis was merely secondary. The miners, who suffered most seriously from the effects of dust, were, of all the classes of workers amongst it, those whom it was most difficult to protect, but their safety would be greatly enhanced by improved ventilation of the mines on well-recognized principles, perhaps by the spraying of them from time to time, so that the dust might be laid, and by the use of flameless explosives that get rid, as far as possible, of carbonic oxide, and by insisting upon long intervals for meals, during which open-air breathing might be enjoyed.

A miner's life is not only dangerous by reason of the chance of accident, but also on account of its menace to health. Unless a coal mine is thoroughly well ventilated, it is obvious that it cannot be a healthy place in which to live. But of all the causes which render picking for coal an occupation harmful to health, no one is more injurious than the constant presence of dust. If some workable plan could be devised whereby the amount of dust might be diminished in coal mines, the lot of the miner would be made far more endurable than it is under the conditions now generally prevalent.

Campaign against the Plague in the Punjab.

The *Indian Medical Gazette*, September, referring to the plague in the Punjab district of India, says: "The Punjab, during the past six plague-stricken years, had, up to 1900—all except a couple of districts—practically escaped. From 530 deaths in 1899-00, the mortality rapidly rose to over 6,000 in the next year, and in the official year 1901-02 the number of deaths rose to the enormous figure of 200,000." Segregation and disinfection have been the means used up to the present to fight the epidemic, but with little or no success. Segregation, under the strict conditions alone useful, is out of the question. Disinfection must also be put on one side, because of the unconquerable dislike of the people to it, for religious and caste reasons, and still more on account of the physical impossibility of disinfecting millions of houses.

There therefore remains only inoculation. When it is considered that the Punjab contains six and a half millions of people, the gigantic nature of the scheme will be readily understood.

Nevertheless, the Punjab Government thinks that the experience which has been gained of the protective effects of inoculation, and the practicability which has been proved, of inducing the inhabitants of the Punjab to submit to it extensively, in anticipation of an outbreak of plague, point to inoculation as a measure on which considerable hope and reliance may be placed. The tremendous experiment in inoculation about to be undertaken in India will be watched with interest everywhere. If successful, or even partially successful, it will be a great triumph for the advocates of the principle of inoculation as a protection against disease.

Medical Ethics.

Medical ethics have been very much to the fore during the past few years. Complaints of unethical conduct are being constantly brought against medical men. Often, however, such faults are committed unwittingly, through the transgressors not having a definite knowledge as to what is really a breach in the observance of the unwritten law of medical etiquette.

The *Edinburgh Medical Journal*, October, takes up the question and discusses it fairly and well. The writer of the remarks to which reference is made says: "There can be no doubt that the general rules of conduct for the medical profession require some authoritative expression of opinion. This feeling is experienced by medical students, as well as by those who are fully fledged. A significant fact which occurred a few years ago may be mentioned. One morning it became whispered abroad that the present popular President of the Royal College of Surgeons, Edinburgh, was about to devote his clinical lecture to medical ethics. The result was that the theater was so crowded that the lecturer could scarcely obtain room in the arena. On his commencing to discuss "hydatigenous moles," or some analogous subject, the anticlimax was too much for the audience—it writhed with Homeric laughter.

The writer goes on to discuss a book recently issued by Dr. Saundby, "Medical Ethics: a Guide to Professional Conduct," and while commending the work as a whole, makes a few criticisms on certain parts of it. Especially are these criticisms directed against Dr. Saundby's suggestion that allopaths should meet homœopaths in consultation—that is, if the latter are duly qualified.

The *Edinburgh Medical Journal* strongly deprecates any steps in this direction, declaring that "Any one who adopts the fetters of an exclusive system of treatment deliberately places himself beyond the pale of scientific methods, and any consultation with such a one must, of necessity, be useless."

Conditions in Great Britain and in the United States are different, and it may be that the feeling of the regular profession with regard to homœopaths is justified there. In New York State whatever prejudice existed against the disciples of Hahnemann is rapidly dying and a spirit of tolerance has taken its place. All graduates of medicine must pass the Regents' Examination before they are allowed to practise in this State, and so are, presumably, on the same plane with respect to medical knowledge.

The *Maritime Medical News*, Halifax, has also an article on medical ethics, and suggests that a short course of lectures on medical ethics should be given to all students in their final year of study. The suggestion is, at least, deserving of consideration.

Insanity and the Negro.

Since the close of the Civil War, and the consequent emancipation of the negro in this country, the prevalence of insanity among the colored race has been extraordinary. A phenomenal increase of mental affections has been observed in those States in which the negro population is largest, and this increase has manifested itself chiefly in those of negro extraction.

Mr. L. Perry read a paper before the Georgia State Sociological Society, at the annual meeting held in Atlanta this year, in which he gave some interesting statistics on the subject.

According to the census of 1860, there were in the State of Georgia forty-four insane negroes. The negro population at that time was 465,698. The ratio of the insane to the total population was 1 to 10,584. In 1870 there were 129 insane negroes in the State, out of a colored population of 545,225. In 1880 the census shows that there were in the State 411 colored insane out of a total of 725,133 or 1 to 1,764. In 1890, according to the census, there were in Georgia 560 insane negroes out of a population of 858,815, or 1 to 1,533. The census of 1900 gives the negro population of Georgia as 1,034,813. The bulletin giving the insane population has not yet been issued, but we can approximate very closely to what it will be. There were in the State Sanatorium on September 1, 1900, 799 colored patients, and, from the number of applications for admission at that time, we may safely estimate that there were at least 100 more insane in the State. Reckoning on this basis for 1900, we find the ratio of insane to the total population to be 1 to 1,149.

Thus, in forty years, the total negro population has been a little more than doubled, while the number of insane has increased twenty-fold. No other such rapid and radical change in the mental stability of a race is recorded in history.

There is every reason to fear that this increase of insanity among the colored race will continue, and probably at a more rapid rate than formerly. Up to the close of the Civil War the negroes of America had been afflicted to a singularly small extent with insanity. Thus at that time heredity was no factor in the causation of the disease. But the remarkable spread of mental affections among the negroes has changed these conditions, and they will now have to contend with predisposition as a probable contributory cause.

The reasons for this proneness to insanity exhibited by the negro inhabitants of the United States lie chiefly in their mental characteristics. At the time when the negro was given his freedom his brain was undeveloped, and he was mentally in no state to be his own master. The sudden plunge into civilization has proved too great a strain for the emotional and child-like nature of the negro, and the consequence has been that his mind, in many instances, has been unable to stand the pressure of excitement and the wear and tear of excess which his freedom has rendered possible.

Modern Life and Disease.

This subject is constantly being made the theme of discussion nowadays. It has been pointed out times without number, that civilization has brought upon us complaints of which our ancestors were almost totally ignorant. These maladies are chiefly those which affect the nervous system, a natural sequence of the high-tension rate of living.

In *World's Work*, October, Dr. Floyd M. Crandall contributes an article upon the diseases of the day, in which he states several instructive facts. He says that "three classes of diseases have increased during the past twenty-five years. These three classes are: degenerations, kidney disease, and cancer. . . . Certain forms of Bright's disease have almost doubled. The power of alcohol in the form of malt liquors to produce degenerative changes is so well known to pathologists that the conclusion is irresistible that the radical increase in these diseases comes largely from changed drinking habits. Conditions which result from the excessive use of distilled liquors have not increased. Cirrhosis of the liver, long known as 'gin-drinkers' liver,' has relatively diminished."

Dr. Crandall says in another part of the article that between 1890 and 1900 the census shows a decrease in the following diseases, per 100,000 population: Consumption, from 245 to 190; diarrhœal diseases, from 104 to 85; diphtheria, from 70.1 to 35.4; typhoid fever, from 46 to 33; membranous croup, from 27 to 9; malarial fever, from 19 to 8. An increase is shown in the following diseases: Pneumonia, from 186 to 191; heart disease, from 121 to 134; kidney disease, from 59 to 83; apoplexy, from 49 to 66; cancer, from 47 to 60; diabetes, from 5 to 9.

The writer points out that the great saving of life during late years, brought about by improved treatment and better sanitation, is not of the middle-aged but of the young. The decrease in infant mortality in cities during the past forty years has been nothing less than phenomenal.

On the whole, then, it may be said that life under modern conditions has been considerably lengthened.

Chiropodists for the British Army.—Recognizing the fact that the care of the soldiers' feet is an important factor in warfare, the British War Office has decided to employ chiropodists in the army. They are to rank not above sergeants, and to perform the duties of enlisted men, but will receive extra pay of 12 cents a day for six days in a week for keeping the soldiers' feet in proper condition

News of the Week

The Berlin Tuberculosis Congress.—The International Congress for the Prevention of Tuberculosis took place in Berlin on Thursday, Friday, Saturday, and Sunday, October 23–26, the meetings being held in the hall of the Prussian Diet. Germany was represented by Professors Koch, von Leyden, and Fraenkel; France, by Professors Brouardel, Calmette, and Nocard; Austria, by Professors von Schrotter and von Dubray; the United States, by Dr. William Eager, and Great Britain, by Drs. Hillier and Theodore Williams. Count von Posadowsky-Wehner, Secretary of the Imperial Home Office, opened the conference. Many papers were read and reports presented.

Prof. Fraenkel reviewed the development of the struggle against tuberculosis up to the time of the establishment of the International Central Committee. In Germany, under von Leyden's influence and direction, a system of sanatoria had arisen for the working classes, and associations had been formed. One of these sanitoria, in the pine woods, distant an hour's railroad ride from Berlin, was visited by the members of the congress, all of whom were loud in their praise of the institution, both for its equipment and for the results of its care of the tuberculous. Prof. Brouardel said that there were now twenty-five public tuberculosis sanatoria in France, the object of which had hitherto, however, been rather isolation than curative treatment of their inmates. The system of sanatoria had, however, entered upon a new era, and every sign of progress in a right direction was evident. Several delegates advised compulsory notification of tuberculosis, and Dr. Hillier submitted the following measures for the prevention of the spread of tuberculosis: (1) The prohibition of expectoration under penalties; (2) Systematic notification of phthisis; (3) Efficient ventilation and lighting in all factories and public and private buildings; (4) The establishment of sanatoria for the treatment of tuberculosis in early and advanced stages.

One of the least practical, but most interesting, papers was one presented by Dr. Kayserling, who showed a series of pictures demonstrating the tuberculous tendency in art. He instanced the case of Simonetta Catania, who served as the model for Botticelli's famous "Venus," in the Berlin National Gallery. She died of consumption at the age of twenty-four years. The speaker said that the whole Botticelli school was strongly influenced by tuberculosis.

On the third day of the congress the proceedings were enlivened by what all had been waiting for, namely, a discussion on the relation of bovine to human tuberculosis. The discussion was opened by Professor Koch in a paper, which was in its conclusions practically a repetition of the one read last year in London. He said that his experiments were not yet complete, but so far as he had perfected them he had not found the slightest evidence that would tend to shake his conviction. He sought to discredit the experiments of de Schweinitz, who had succeeded in transmitting tuberculosis to calves by inoculation with material from a tuberculous human being, saying that the experiments were too hasty and that sufficient time had not elapsed to allow of positive conclusions being drawn. He added that the American literature on the subject of bovine and human tuberculosis was one-sided, and often couched in terms such as might be used by a lawyer, who, in defending a criminal, would suppress all points telling against his client. Professor Nocard of Alfort spoke on the other side. He said Koch's assertions, if true, would lead to the conclusion that all precautions against the transmission of tuberculosis from the lower animals to man were unnecessary. But a number of experiments made since the delivery of Koch's sensational address in London proved conclusively that beasts could be infected by human tubercle bacilli. The speaker said he himself had killed five monkeys through inoculation with bovine bacilli, and he asked why human beings should be immune. He said he regarded the danger from tuberculous animals as established, and he declared that such animals should be destroyed and those suspected of being infected should be isolated. Other papers were presented by the supporters and the opponents of the doctrine of the practical identity of human and bovine tuberculosis, but no new facts or arguments were brought forward.

At the final session of the congress, held on Sunday, Dr. Williams of England made an address in which he advocated the classification of patients in sanatoria according to the progress each makes toward recovery. The congress then adjourned. It will meet next year in Paris. On the whole, the congress seems to have been rather barren of results, but perhaps not more so than most gatherings of the sort.

A Suit for Damages for X-Ray Burns.—Suit has been brought by a brewery employee against a physician of this city to recover $50,000 damages for a dermatitis alleged to have resulted from an *x*-ray examination. The man had some abdominal trouble and was subject to a Röntgen examination, after having been warned of the possibility of a burn and having given his consent. As a result of the examination a diagnosis of probable relapsing appendicitis was made and this was confirmed at the operation, when a diseased appendix was found and removed. The man subsequently suffered from a dermatitis of the abdomen, and claimed that it was caused by carelessness of the physician taking the radiographs. The fact of a dermatitis is not denied by the defense, but the claim is made that all possible care was employed in the examination, and that the inflammation was caused by strong antiseptic applications made prior to the operation.

A Year of Freedom from Yellow Fever in Havana.—In the recently-issued report of the Chief of the Sanitary Department in Havana, Dr. Charles Finlay, the announcement is made that, with the end of September, an entire year has passed in which not a single case of yellow fever, so far as known to the authorities, has originated in Havana. Such a period of immunity has not been seen before in one hundred and forty years. During five months of the twelve, and these among the most dangerous months, the sanitary department has been under Cuban control, so that, so far as Havana at least is concerned, the fears that the health conditions established by the medical officers of the United States Army would be allowed to deteriorate have not been realized. Dr. Finlay has earned the gratitude of our seaboard population, especially in the south, for keeping off the menace of a fever-ridden Havana by his efficient administration of the health department of that city.

The Plague in San Francisco continues to claim its victims in spite of, or maybe in a measure because of, the reiterated official denials of its existence. During September ten cases were added to the list of deaths from bubonic plague, bringing the total, to October 1, up to eighty-one. In every instance the diagnosis is confirmed by autopsy. The *Occidental Medical Times* says that the "Public Health and Marine-Hospital Service is notified promptly as the cases occur, the State Board of Health is immediately informed of a death, and usually has a representative present, who is supposed to state the facts; while the local board is at the mercy of a mayor and a governor, who scowl at the mention of their existence. Our only appeal therefore is to the health boards of the country at large and the possibility of the election of a governor whose honesty will rise above the dictations of politics and money to the welfare of our people and that of the other States of the Union."

A Specific Pertussis Serum.—Dr. Leureaux of Brussels claims to have prepared an anti-pertussis serum of therapeutic value. He asserts that he has used the serum in a number of cases, and has succeeded in cutting the disease short within a week or ten days, when the injections were given at an early stage. The first effects are manifest at the end of from thirty-six to forty-eight hours, the paroxysms of coughing being markedly reduced.

Heart Suture.—A woman was stabbed in the heart last week and taken to Bellevue Hospital, where the cardiac wound was successfully sutured by Dr. George D. Stewart. The woman died some days after the operation of septic poisoning, the source of infection being the knife employed. The autopsy showed union of the wound in the heart muscle. A similar operation was reported by Dr. Luther L. Hill of Montgomery, Ala., in September. The patient was a negro boy, thirteen years old, who had been stabbed by a companion. There was a wound half an inch in length in the wall of the left ventricle, which was closed by catgut sutures. The boy made a perfect recovery, and was shown to the members of the Southeast Alabama Medical League at a meeting in Dothen last week.

Dr. Lorenz Breaks a Leg.—In operating on a child at Mercy Hospital, Chicago, on Wednesday of last week, Dr. Adolf Lorenz fractured the patient's femur. According to the daily press, which fully and carefully chronicles all his professional labors, the surgeon was in no way disconcerted by the mishap. He merely stopped the operation and explained that the accident was the tenth that had occurred in the course of his caring for more than 1,000 cases of dislocation of the hip. "It postpones the operation," he said (so runs the newspaper account), "but in no way affects the ultimate outcome. In fact, the patient is in better condition than before the fracture, and there is better assurance of her complete recovery from the deformity."

Christian Scientists Arrested for Manslaughter.—A child died of diphtheria in White Plains, N. Y., last week. The Chrisian Science healer, who attended her for one dollar a visit and carfares, said she had a "claim" of tonsillitis, but the "claim" of the coroner that the disease was diphtheria was stronger, and so the healer was held for manslaughter. With him were also held the child's parents on the same charge, but the mother's arrest was technical only, as she and another of her children were sick at their home with diphtheria caught from the child who died. There are other cases of diphtheria in the town which are directly traceable to the same source.

St. Luke's Hospital.—At the annual meeting of the Board of Managers of St. Luke's Hospital in this city on St. Luke's Day, October 18, the report for the year ended September 30 was read. It announced that 2,663 persons had been treated; of these, 1,536 had been discharged as cured, 434 discharged as improved, 75 discharged unimproved, 292 had died, and 201 remained in the hospital. The number of hospital days was 73,556. The training school for nurses was reported to be in a satisfactory and flourishing condition, with seventy-eight in it at the close of the year.

A Report on Plague.—A cable despatch to *The Sun* from London states that the Local Government Board has just issued an important volume, giving the results of an investigation of the bubonic plague in all parts of the world for the last three years. A curious feature of the disease is its mimicry of other affections when it first invades a new region. The plague when it first appeared in a new field often presented curious resemblances to some commonplace current malady, such as influenza, typhoid fever, or malaria. Repeated mistakes were made in the diagnoses at the beginning of the outbreaks not only where the plague was not looked for, but in countries where the officials and practitioners were alert in watching for it, and believed that they were prepared to detect its appearance. The records tend to confirm the belief that man and rat are reciprocally infective, yet they fail completely to afford sufficient data for determining the degree that man is in danger through the rat. In some localities man and rat suffered at the same time. In other localities the man suffered before the rat, and in still others the rat was attacked first. Moreover, when in a particular district either the man or the rat was the first to suffer, the interval between the invasion from the first to the second species has often been long, extending for weeks and months. Finally, it would appear that the plague may prevail largely among men without rats being affected, and, conversely, among rats without men being affected.

General Addresses at the Madrid Congress.—The following addresses will be delivered at the general sessions of the Fourteenth International Medical Congress, to be held in Madrid, April 23–30, 1903: S. Laache of Christiania, on "Reciprocity in Pathology"; Ivan Petrovitch Pavlov of St. Petersburg (subject to be announced); Arthur Thomson of Oxford (subject to be announced); Wilhelm Waldeyer of Berlin, on "Phylogenic Theories and Darwinism"; Eduardo Maragliano of Genoa, on "The Struggle of the Organism against Tuberculosis"; P. Brouardel of Paris, on "Adulteration of Food"; A. Politzer of Vienna, on "The Necessity of the Official Teaching of Otology"; Rodriguez Carracido of Madrid, on "Pharmacological Complexity in Medical Prescriptions"; Santiago Ramón y Cajal of Madrid (subject to be announced); Rafael Rodriguez Mendez of Barcelona (subject to be announced); Howard A. Kelly of Baltimore, on "Urinary Infection"; Juan Santos Fernandez of Havana on "Diseases of the Eyes in the Tropics"; Emilio R. Coni of Buenos Ayres, on "Public Medicine in South America."

Hospital for the St. Louis Exposition.—It is planned to erect a permanent hospital building for use during the St. Louis World's Fair in 1904, and to give it to the Washington University at the close of the exposition. The hospital will be built on cht university property adjoining the fair grounds, in a style in keeping with the university buildings already in existence.

Statement of the Commission in Lunacy.—The New York State Commission in Lunacy has issued a statement declaring without foundation in fact the assertions recently made by political opponents of the Governor regarding the State hospitals. These assertions were to the effect that, owing to decreased appropriations, the efficiency of the State hospitals for the insane had been seriously impaired, that scurvy had resulted from diminished food supply, and that the hospital officials had in various ways been intimidated. The Commission defends the changes made in the pathological department, and says that, in consequence of the improved methods of research introduced by Dr. Meyer, there is reason to hope that at no distant day tangible results will be manifest in an enhancement of the recovery rate. It is admitted that the hospitals are overcrowded, but it is asserted that if the contractors having buildings now in course of construction, adequate appropriations for which have been made, had complied with the terms of their contracts requiring the completion of the buildings during the present year, the accommodations thus provided would have met every requirement. No case of scurvy, the Commission says, exists or has existed in any State institution since the inauguration of State care, so far as can be learned by those in responsible charge of the hospitals. It can be asserted that at this time, and for several months past, the insane of this State are receiving a better quality, quantity, and variety of food than any similar class of persons are receiving anywhere in the United States. Regarding the intimidation charge, the report says that the system of rules and regulations which has been prescribed by the Commission and approved by the Governor was prepared by the medical superintendents themselves—the very slight modifications therein having been made by the Medical Commissioner, Dr. Frederick Peterson.

Charges of Grave Robbery in Indianapolis.—A number of cases of "body snatching" have been the subject of investigation in Indianapolis, and a week ago the Grand Jury brought twenty-five indictments. Five of these were against physicians, who were charged with complicity in the grave robberies in failing to keep records of the bodies received. According to the testimony of one of the men accused, over one hundred bodies have been stolen from cemeteries in the neighborhood of the city during the past year.

The Plague in Odessa.—The city and provincial authorities have become alarmed at the continuance of the plague in Odessa, and have taken energetic measures to avert the threatened epidemic. Many old wooden buildings in the market place, which were infested with rats, have been burned, and war is being waged against the vermin in all parts of the city and in the harbor. The city government has appropriated 25,000 rubles, equivalent to about $12,500, monthly to provide medical assistance, and it has been determined to keep the public informed regarding the progress of the disease and the measures taken to combat it. The deaths number only fifteen, yet all this is done in Odessa; in San Francisco the deaths number over eighty, and nothing has been done.

Treatment of Unconscious Patients by Ambulance Surgeons.—A man in Brooklyn, who was knocked down by a trolley car, was examined by an ambulance surgeon, who diagnosed a case of simple alcoholism. The man was locked up, but, failing to recover from his "alcoholism," he was subsequently removed to the hospital, where he died of a fractured skull. To prevent such occurrences in future, a health department order has been issued, directing ambulance surgeons in that borough to take all persons suffering from partial or complete loss of consciousness to the nearest hospital, whether they are apparently under the influence of alcohol or not.

Free Consumptives' Clinics in Philadelphia.—Through the generosity of Mr. Henry Phipps, formerly of Pittsburg, but now of New York, several free clinics for the treatment of tuberculosis are to be established in Philadelphia. The gift of a large sum has already been made for the purchase of ground and erection of buildings,and a further donation for the maintenance of the clinics is promised. The clinics will be under the charge of Dr. Lawrence F. Flick, who is at the head of the Sanatorium for Poor Consumptives in Luzerne County, Pennsylvania.

Dr. T. D. Crothers of Hartford, Conn., has been elected consulting Neurologist by the Board of Trustees of the New York Metropolitan Hospital and Dispensary.

Philadelphia Pediatric Society.—At a stated meeting, held October 14, Dr. D. L. Edsall reported a case of tuberculous meningitis without focal symptoms. The child exhibited a marked tetanoid condition, with convulsions on the slightest provocation, but there was no retraction of the head and no Kernig's sign. The convulsive seizures were temporarily allayed by lumbar punctur, performed for diagnostic purposes. After death internal hydrocephalus was found, all of the ventricles of the brain being greatly dilated, with tuberculous meningitis at the base of the skull from the anterior portion of the medulla forward, as well as miliary tuberculosis of lungs and spleen. Attention was called especially to the frequency with which retraction of the head and Kernig's sign are absent in cases of tuberculous meningitis. Drs. A. H. Davisson and D. J. McCarthy presented a communication entitled "Autopsy Report of a Case of Spinal Paraplegia in the New-born." The case had been one of difficult labor, with head-last delivery, and not a little traction had been made in the extraction of the child. To this circumstance the mother attributed the flaccid paraplegia that was observed. Post-mortem examination disclosed an attenuation of the cord below the cervical and above the lumbar enlargement, and this, on section, was shown to be due to destruction of the cord, in consequence of an extensive extravasation of blood into its structure. It could not be stated with certainty whether the hemorrhage was due to the traumatism at birth or had existed previously, although the probability seemed in favor of the former. Dr. Thompson S. Westcott read a paper entitled "A Suggestion for Greater Clearness in the Designation of Milk-dilutions." He pointed out the want of uniformity in the description of milk-mixtures, and, in order to avoid ambiguity and uncertainty, he proposed that the degree of dilution be expressed in terms of the number of parts of milk in the total mixture. Thus one part of milk and an equal part of diluent would be spoken of as one in two; one part of milk in four parts of diluent as one in five, and so on. Dr. J. Herbert McKee reported a case of cerebellar tumor from an infant of eighteen months. He also demonstrated a specimen from a patient with congenital cardiac disease. The little patient exhibited marked cyanosis and various murmurs during life, while after death the interventricular septum was found deficient and with a large opening, the valve of Botal was closed imperfectly, the arterial duct was persistent, the pulmonary orifice was constricted and the pulmonary valve was constituted by a single leaflet. Dr. McKee reported also a case of intubation at a very early age. The patient was a child but a few days old, presenting symptoms of obstruction of the lower air-passages, but the operation failed to afford permanent relief. After death marked pulmonary œdema was found. The condition is thought to be due to an attempt at infanticide, possibly by strangling, on the part of the mother, who was unmarried. Dr. McKee presented, further, notes upon a case of probable duodenal atresia. There was persistent vomiting, but an autopsy could not be secured, and the diagnosis, therefore, could not be verified.

New York Academy of Medicine; Anniversary Meeting.—The annual meeting of the Academy will be held on Thursday evening, November 6, at 8 o'clock. Dr. Andrew H. Smith will deliver the anniversary address on "The Past, Present, and Future of the New York Academy of Medicine." Following this, Major William C. Gorgas, U. S. A., Chief Surgeon of the Sanitary Department of Cuba during the American occupation, will read a paper on "The Disappearance of Yellow Fever from Havana."

College of Physicians of Philadelphia—Section on General Medicine.—At a stated meeting, held October 13, Dr. Augustus A. Eshner exhibited a case of gliomatosis. The patient was a woman, forty-five years old, in whom, together with paresthesiæ, there was, in the upper extremities, in more marked degree on the right, impairment of tactile, painful, and thermic sensibility, in varying degree, up to the point of complete obliteration, in different situations, also muscular wasting and contractures, and exaggeration of the knee-jerks, with ankle clonus on the right side. The right pupil and the right palpebral fissure were smaller than the left, and the activity of movement was greater on the left than on the right side of the face. The symptoms had been present for several years, were progressive in character, and there was no known etiologic factor. For these reasons, together with the period of life at which the symptoms had set in, the condition was looked upon as one of gliomatosis, involving the uppermost portion of the spinal cord, and, possibly, also the medulla in some degree, probably followed by breaking down of the new-formed tissue, with the formation of a cavity. Dr. David Riesman read a paper entitled "Hemopericardium, with the Report of a Case Simulating Mediastinal Tumor." The patient was a man, who presented symptoms of cardiac insufficiency, with cyanosis and an increased area of cardiac percussion-dulness, with marked transmission of the heart-sounds and signs suggestive of pneumonia at the left base. Puncture of the pericardium disclosed the presence of blood-stained fluid. Dr. Herman B. Allyn related a case of hemorrhagic pericarditis in which aspiration of the effused fluid was followed by relief. Dr. J. Alison Scott referred to a case of hemopericardium, due to rupture of a sinus of valsalva. Dr. D. L. Edsall spoke of a case presenting enlargement of the area of cardiac percussion-dulness following removal of a fibroid tumor of the uterus, in which the condition was thought to be due to hemopericardium, or acute dilatation of the heart. Dr. J. Alison Scott read a paper entitled "A Case of Acute Intestinal Obstruction Caused by a Large Gallstone; Operation and Death." The patient was an elderly woman, with a history of previous attacks of biliary colic, and the operation was performed for the relief of intestinal obstruction not yielding to ordinary therapeutic measures, and disclosing the presence of a large calculus obstructing the lumen of the bowel, and associated with beginning necrosis of the intestine above the point of occlusion. Resection of the bowel was undertaken, more than a foot of intestine being removed, but the patient failed to react and death resulted. The stone was ovoid in shape, unfacetted, and it consisted principally of cholesterin. Dr. Addinell Hewson referred to a case in which a large gallstone ulcerated its way through the walls of the gall-bladder and the duodenum, and became lodged in the small intestine not far from the ileocæcal valve. The family of the patient long declined operation, but finally, the calculus was removed, but death occurred. Dr. David Riesman referred to a case in which obtruction of the bowel existed and was thought to be due to mechanical causes. Operation was urged and acquiesced in by the surgeon called in consultation. The patient, however, declined. Accordingly, opium was administered and relief from the obstruction followed.

The Pope's Physician, Dr. Lapponi, was successfully operated upon for appendicitis on Sunday of this week, by Dr. Mazzoni, the same physician who assisted him in a slight operation on the Holy Father about two years ago.

The National Association for the Study of Epilepsy and the Care and Treatment of Epileptics will meet in annual session at the Academy of Medicine in this city at 2.30 P.M. on Wednesday, November 5. The program contains many papers of great practical value and interest, among the contributors being Drs. Frederick Peterson, Adolph Meyer, Roswell Park, H. N. Moyer, L. P. Clark, Thomas Prout, W. P. Spratling, and Wm. N. Bullard. Physicians and charity workers generally are invited to attend the meetings. The association was founded to promote the general welfare of sufferers from epilepsy; to stimulate the study of the causes and methods of cure of this disease; to advocate the care of epileptics in institutions in which they may be educated, acquire trades, and be treated by the best medical skill for their malady, and to assist the various States in making proper provisions for this class. The association has no membership dues. Applications to join it should be made to Dr. W. N. Bullard, chairman of the executive committee, 89 Marlboro street, Boston, or to Dr. W. P. Spratling, secretary, Sonyea, N. Y.

Philadelphia County Medical Society.—At a stated business meeting, held October 15, in addition to election of members, nomination of officers, reception of the reports of the nominating committee, of the censors, and of the delegation to the Medical Society of the State of Pennsylvania, the following amendments to the by-laws of the society were adopted:

SECTION 1.—Within fifteen days after the business meeting in January, the Board of Directors shall appoint an attorney-at-law for the term of one year, who, in addition to representing this socety in all suits for malpractice and threats against its members as hereinafter provided, will assist the district attorney in prosecuting illegal practitioners of medicine and representing the society in other legal affairs.

SECTION 2.—The Board of Directors may, upon request and in compliance with the conditions hereinafter named, assume the defence of suits for alleged malpractice brought against members of this society.

SECTION 3.—The Board of Directors shall not undertake the defence of any suit based upon acts prior to the qualification of the accused as a member of the society.

SECTION 4.—Any member desiring to avail himself of the provisions of this article shall first present his case to the Board of Censors, who shall decide upon the validity of his claim. He may then make application to the Board of Directors through the secretary, shall sign a contract renouncing his own and vesting in the Board of Directors sole authority to conduct the defense of said suit, and shall make such other agreements as the Board of Directors may require. *Provided*, That nothing in the foregoing shall conflict with united action in the defense by the officials of any corporation organized for this specific purpose, with which a member may be connected.

Section 5.—The Board of Directors shall thereupon contract with said applicant to take full charge of said suit, to furnish all necessary legal services, to furnish all medical expert services, and to pay all necessary expenses of the accused. *Provided*, That if the accused is insured in a corporation organized for the legal and financial defense of physicians, the foregoing responsibility of the Board of Directors may be divided with said corporation. The Board of Directors shall not obligate the society to the payment of any damages awarded by decree of court or upon compromise.

Section 6.—The Board of Directors shall have authority to name the sum for the compensation of the attorney.

Obituary Notes.—Dr. Thomas G. Underwood of Brooklyn died on October 19 at the age of sixty-three years. He was born in Castleton, Vt., but went to Brooklyn when a young man and became a clerk in a pharmacy. While there he studied medicine and obtained a degree, but continued in business as a druggist.

Dr. James D. Wade of Brooklyn died suddenly on October 19 while writing a prescription at the bedside of a patient. Just before leaving his home he had been informed of the death of Dr.. Underwood, a life-long friend, which affected him deeply. He was born in this city in 1838. During the civil war he served with distinction in the line, and, after receiving his discharge, took up the study of medicine, receiving his degree from the New York University Medical School in 1866.

Dr. Henry C. Matthews of Brooklyn died of apoplexy at Clifton Springs on October 21. He was born in Vermont in 1841, and was graduated in medicine from the University of Vermont in 1869.

Dr. William E. Doughty died at Hartsville, Pa., on October 15 at the age of sixty-six years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1868, a veteran of the civil war, and a member of the Bucks County Pension Examining Board.

Dr. Francis E. Martindale died at his home in Port Richmond, New York City, on October 26, at the age of seventy-two years. He was a graduate of the Albany Medical College in the class of 1853. He retired from active practice several years ago.

Dr. William Young died at his home in Cold Spring-on-Hudson, N. Y., on October 26, at the age of eighty-two years. He was born in Portglenone, Ireland, in 1820, but when two years old was brought to this country by his parents. He studied medicine in Scotland and was graduated from the University of Glasgow in 1842. After a time spent in post-graduate study in Dublin and Vienna he returned to this country and practised for a while in New York City, going later to Cold Spring. Dr. Young was the last surviving charter member of the New York Academy of Medicine.

Statistical Inquiry.—A committee has been appointed by the Council of the Royal Statistical Society for the purpose of inquiry into the production and consumption of meat and milk in the United Kingdom. One very important side of this inquiry is that which involves the collection of statistics as to the consumption of these articles of food by private householders. The committee is particularly anxious to secure a very large preponderance of returns from the laboring classes and small consumers.—*Public Health.*

OUR LONDON LETTER.

(From Our Special Correspondont.)

HUXLEY LECTURE—MEDICAL EDUCATION IN THE NEW UNIVERSITY—SURGICAL ADVANCES—PAY PATIENTS IN INFECTIOUS HOSPITALS—ROYAL ORTHOPÆDIC HOSPITAL—FIRES IN HOSPITALS—CHEMIST'S DANGEROUS PRESCRIBING,

London October 10.

The Huxley lecture has been a very successful institution. The fourth was given this year by Professor W. H. Welch of Johns Hopkins University, and it is gratifying to us to have heard so prominent an exponent of American medical science. But I will not pretend to estimate his distinctions or the value of his work. They are better known, perhaps, to you; though science being of no country we, on our side, could not be altogether ignorant of what he has done. He began with an expression of some embarrassment at undertaking to follow his three predecessors, Michael Foster, Virchow, and Listen. But he soon passed to a few words on Huxley, and quoted from the son's "Life and Letters," a valuable testimony to the late Wharton Jones, who taught physiology at Charing Cross Hospital when Huxley was a student there. Then he paused to pay a tribute to Virchow, whose recent death leaves such a blank. The Huxley is required to be devoted to recent advances in science, and their bearing upon medicine and surgery. Accordngly Professor Welch chose for his subject, "Recent Studies of Immunity, with Special Reference to their Bearing on Pathology." He dwelt more particularly on some aspects of the subject which he thought might be less familiar to physicians unless they have closely followed recent researches in this department. Needless to say that to compress a condensed review of so abstruse a subject would be impossible in a letter, and if it were possible your readers will be well acquainted with some of the points made, while as to others, those who follow such investigations will have an opportunity of perusing the lecture, for two of our journals have announced that they will issue it *in exenso* to-morrow. Professor Welch uses as a working hypothesis Ehrlich's side-chain theory, but not altogether without some modification. How he has himself applied it, and what he suggests as the benefits likely to accrue to humanity, were stated with great lucidity, and the lecture may be regarded as an up-to-date statement of the position of immunity.

It was only natural for the position of the reconstructed London Unversity in relation to medicine to be glanced at in some of the ceremonies of the opening session. At St. Mary's Hospital Sir A. Rucker, the principal of the university, distributed the prizes, and expressed a hope that his presence was a good omen for the future relations between the school and university. He said it had long been one of the most scandalous anomalies of London that there was no teaching university in its midst, and until recently the metropolis was inferior in this respect to other cities. The new system made it possible for a medical student to enter on a university course.

The question was looked at from a different point of view by Mr. Flemming at University College. He remarked that after much travail a new university was born a year or two ago, and the feeding of this infant is being watched by many experts—the chief food needed being money, without which it may live, but cannot thrive. Now it occurred to some that it might assist matters to give some of the food in a predigested form, and so the college and its equipment had been offered to the infant university instead of actual money. But the expert attendants thought the entire college might prove too much for the infant's constitution, the particular part of the college likely to disagree being the medical faculty. Now negotiations are still going on, and many rumors are floating about, but at present no result has been reached. Mr. Flemming remarked if the medical faculty ceased to be a part of the college, it would not go out empty-handed. It would have the hospital—the latest, newest, and best equipped hospital of the largest city of the world—and it would carry its traditions of the school, which boasted of names such as Cooper, Liston, Marshall, Tuain Wilson Fox, Marcus Beck, Jenner, Walsh, Hare, Russell, Reynolds, not to mention those still working there.

Whatever may be the conclusion of the negotiations as to University College, there can be no doubt that the new university will exercise the predominant influence over medical education for a long time to come. I may as well, therefore, tell you of some of the points that are so far practically decided. The teaching of anatomy and physiology is to be concentrated into two or three centres instead of the existing twelve schools. Whether these subjects will be better taught is an open question, for the ability and devotion displayed by some of the past teachers cannot be surpassed. No doubt the fewer institutions may give more remuneration to the teachers employed, but the change must necessarily leave others unemployed. Howbeit the university is committed to "concentration," and there is to be established near it an institute of medical sciences second to none for the training of medical students; that is, provided the money can be obtained. The clinical instruction must, of course, continue to be carried out at the hospitals. Incidentally, it is probable that the number of examinations that students will have to pass will be diminished, and a good degree will be attainable by all who have faithfully worked through the curriculum.

The matriculation examination has been rearranged on the broadest lines, and will be the one portal through which every student must enter the university whatever faculty he may wish to proceed in—and we are threatened with a number of new faculties. Latin, as I have told you, becomes an optional subject, but it is to be hoped all medical students will select it, though, perhaps, some Eastern gentlemen may choose Arabic, Sanskrit, or any other language in the list.

At Leeds Mr. Mayo Robson gave a luminous account of the advance of surgery during the last thirty years, but while as a surgeon he exalted his own art, he did not disparage medicine. On the contrary, he said that just as the surgeon has taken over the treatment of certain cases of disease in the brain, chest, and abdomen, so he looked for the day when the physician, in his turn, might take over the treatment of cancer. Already rodent ulcer is passing from the domain of surgery proper and being cured by Röntgen rays. Even the treatment of epithelioma, a more rapid form of malignant disease, is, in some cases, yielding to similar treatment, as shown in the Leeds infirmary. But as yet surgery is the sheet anchor in most cases of cancer, and when treated radically and early enough, many patients live active and useful lives for many years after the removal of undoubted cancer.

The recent discussions on paying patients in hospitals seems to have suggested to the Asylums Board that they might very well provide more privacy in their fever hospitals for patients who would willingly pay for it; in fact, would prefer to do so. A resolution in this sense has been adopted, and it is hardly likely that the Local Government Board will withhold its consent. There really seems no reason why infectious patients should be taken care of at the ratepayers' expense when they are anxious to bear their share of the cost if only they can have more privacy and a few minor comforts to which they are accustomed.

The history of the Royal Orthopædic Hospital reflects no credit on its managers, and the recent proceedings to which I have more than once alluded, show that the present board is unfit to conduct its affairs. They have lately, after about two years' urging, issued a statement of which business men should be ashamed. On the pretence that the freehold site was too valuable to retain, they have agreed to sell it for less than they might have obtained. The opposition to the sale increased the price by £12,000, but still more might have been had if the matter had been properly attended to. Now they are to remove, rebuild on a leasehold site at a rental of £500 a year. It is said that the charter has been disregarded, and the courts might set aside the sale if any one was interested enough to litigate. It would certainly be a good thing if the managers could be held personally responsible for squandering the most valuable asset of the institution.

In my last letter I mentioned that a fire had occurred at Addenbrooke's Hospital, Cambridge. A similar occurrence has since been reported elsewhere, and some uneasiness is felt as to whether this danger is properly provided against in our great hospitals. There is a feeling of relief when reading that only some property was destroyed, the patients being all safely removed; but there is also a foreboding of a tragedy that may be impending. The mere necessity of removing patients on account of an outbreak of fire must be very injurious to them from the shock and alarm caused. What would the consequence be of a great fire in a hospital or asylum, or even close by? From various circumstances I fear that in some directions the danger is not fully appreciated.

The risks cheerfully run by prescribing chemists were illustrated at an inquest the other day. One of these unqualified persons had prescribed and dispensed prussic acid. A verdict of misadventure saves him from a trial for manslaughter, and the public will, no doubt, continue to patronize prescribing druggists.

THE EYE-FACTOR IN SEA-SICKNESS AND OTHER TYPES OF VERTIGO.

To the Editor of the Medical Record

Sir: In your issue of October 11, 1902, appears a clinical article by Dr. E. Castelli of Washington, D. C., entitled "A New Theory in Regard to Sea-sickness." In fairness to others, I must say that that title is misleading.

For many years (prior to 1890, I think) I incorporated in my annual lectures before the medical students of the University of Vermont and the Post-graduate Medical School and Hospital of this city positive demonstrations of the fact that the eyes are an important, and too often, an unrecognized factor in causing both vertigo and sea-sickness.

I say "fact" instead of "theory," because the time has passed, in my opinion, when that statement can be intelligently questioned or disproved.

Quite a large proportion of the human race can be made to be not only dizzy but actually nauseated by various forms of visual impressions. Even a strong plus-glass on some children (if persistently worn for a few minutes) will frequently cause a marked feeling of nausea. Gazing from a height affects many people seriously—causing vertigo and nausea of a pronounced type. Looking at a waterfall, or at any rapidly revolving object, will also make a certain proportion of children and adults both dizzy and sick. The condition known as "car-sickness" is unquestionably excited, in many instances, by looking at rapidly-moving objects through the window of the car.

There is positive clinical evidence to-day that abnormal conditions of the eyes and the eye-muscles can not only excite attacks of faintness, extreme nausea, and vomiting, but even epileptic seizures.

I have reported during the past fifteen years, in various medical journals, many absolute and permanent cures of persistent and uncontrollable vomiting, fainting attacks, car-sickness, and epileptic seizures without the use of drugs, simply by the correction of congenital defects in adjustment of the eyes to each other. In my late work entitled "Eye-strain in Health and Disease," published by F. A. Davis Co. of Philadelphia, I have gone extensively into the physiological basis of such symptoms and their rational treatment; and I have published in that work complete clinical reports of a large number of illustrative cases in support of the views therein advanced.

There is another factor that bears a relationship to sea-sickness, which is, perhaps, almost as important as the ocular factor. I refer to abnormal conditions of the general muscular system produced by both unconscious and voluntary efforts on the part of the sufferer to adjust the body as well as the eyes to the ever-varying conditions entailed by the motion of the ship. In 1884 Drs. F. X. Dercun and H. A. Parker of the University of Pennsylvania published in the *Journal of Nervous and Mental Disease*, pp. 579 and 636, some very remarkable experiments to show that general convulsive seizures, closely allied to epilepsy, could be artificially produced in healthy subjects by prolonged muscular tension of a single muscle or groups of muscles in the limbs. These experiments have been frequently confirmed by other observers.

The physiology of sea-sickness is, unquestionably, this: The eyes first give information to the sufferer of the changing of horizons produced by the movement of the vessel. The sufferer immediately begins unconsciously to adjust both his eyes and his body to varying planes to which he is being subjected. He struggles, in consequence, to adapt himself to conditions which he cannot anticipate and prepare for, until, at last, he loses the normal control over his nervous mechanism, and experiences the reflex nervous conditions manifested by dizziness and nausea.

Even when the prone position in the bunk is sought, and the eyes are closed, the involuntary effort of the patient to adjust his trunk and limbs to unexpected rolling and pitching motions of the ship tend to keep up these reflex nervous disturbances until the patient becomes too weak to make such efforts or the motions of the vessel cease. Then the nervous equilibrium becomes reestablished gradually, and the nausea and vertigo subside.

Why some people become easily seasick and others do not is simply a personal equation. Those who are most susceptible to reflex ocular disturbances are almost invariably those who are victims to "heterophoria" (a term that covers all the different forms of congenital muscular unbalance in the orbit). Whenever the eyes of such patients are properly examined by modern methods, and the eye-muscles scientifically adjusted to the normal standard, it is not uncommon, in my experience, to see car-sickness, sea-sickness, vertigo, persistent nausea, and fainting attacks materially modified or made a thing of the past.

The following suggestions relating to the prevention of sea-sickness, car-sickness, vertigo, and nausea will prove of great practical benefit to sufferers of this class:

1. Have the eyes carefully examined for errors of refraction and muscular unbalance (heterophoria), in order to ascertain what abnormal eye-factors exist. These tests should be made by modern methods and with modern apparatus, which insure scientific precision.

2. Any abnormal eye-factors found should be corrected before there is any recourse to drugs.

3. Patients who are peculiarly susceptible to sea-sickness or car-sickness should be instructed to make no efforts of visual-adjustment or of body-adjustment that they can possibly avoid for the first part of their trip. They should not look out of windows or port-holes. They should school themselves to assume the condition as closely as possible of absolute passiveness to all surroundings. This applies to the body as well as to efforts of vision. I instruct my patients to "put themselves in the condition of a person who is stupidly drunk" so long as they feel uncertain of their nervous equilibrium and control.

4. The scheme of looking in a mirror (which tends to prevent the visual impression of changing horizons); the use of red glasses or other befogging media; the prone position, as soon as the trip is begun; and various other suggestions of that character, that have been published from time to time, are not unique or particularly efficacious, unless combined with an effort on the part of the sufferer to keep his general muscular system absolutely passive.

When a sufferer from sea-sickness begins to regulate his breathing and abdominal movements to the ship's motion; when he begins to make various sets of muscles tense in anticipation of some changed position of the ship; when he begins to wonder how long he can last without vomiting, when he is going to vomit, and how long he is to continue; and when he begins to feel that the fight is a hopeless one, he will surely get a case of nervous "rattles," lose the governor to his nervous mechanism, and have all that he anticipates, in spite of drugs or other suggestions of relief.

345 Madison Avenue New York City.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 23, 1902.

Decapsulation of the Kidney for Nephritis.—J. W. Elliot reports two cases. In the first the patient has improved greatly since the operation, the œdema and headache are gone, there have been no convulsions, and he feels splendidly. The blood tension seems to be lower. In the second case there has been little or no improvement, except that the patient seems brighter. A curious point in both these cases is that ether seemed to do them no harm. We used to be afraid of giving ether in cases showing kidney trouble, especially in those with œdema, but in these cases, although they were of the worst type, the operation did not upset the patient at all. The total amount of urine was reduced for only one day, but after that returned to normal. On the whole, the operation seems to be a safe experiment.

Deciduoma Malignum. J. C. Hubbard reports a case of this most malignant of all malignant tumors. Diagnosis is made from the excessive hemorrhages following after some form of conception, and not yielding to the treatment appropriate for retained portions of the pregnancy, endometritis, metritis or subinvolution, the marked cachexia, a uterus enlarged and boggy, containing a friable, soft, easily-bleeding tumor, and from the microscopic examination of a bit of the tissue. The only hope of cure is in an early diagnosis, and the only effective treatment consists in hysterectomy. Whether it shall be by the vaginal or the abdominal route must depend on the choice of the operator and the peculiarities of the individual case. Nothing less radical offers the least hope of cure, and is only wasting valuable time.

Decapsulation of the Kidneys.—A. T. Cabot reports two cases operated on by stripping off the capsule of the kidney, the kidney being afterward dropped into place. The clinical history of the first patient, a man, suggested an interstitial nephritis, while the second, a woman, seemed to be suffering from a chronic parenchymatous nephritis. The operation was well borne in both cases. The man made a good recovery from the ether, his wounds healed quickly, his general condition improved, and in less than a month he was sitting up. Then, suddenly, with no warning except a reappearance of irregularity and intermittency in the pulse, the patient died. The condition of the kidneys was found to be markedly arteriosclerotic. The second case is decidedly improved, her headaches having disappeared, and a certain amount of strength having been recovered. After both operations the quantity of urine was increased, and the number of casts was diminished, but in neither had the casts of albumin wholly disappeared.

Journal of American Medical Association, October 25, 1902.

Trichophytosis.—J. B. Kessler thinks that a frequent source of the trichophyton is cattle, and especially yearling calves. The farmer handles his stock, becomes infected, goes to the barber shop to be shaved, and thus spreads the infection. Several cases are mentioned confirming this view of the spread of the malady.

The Surgical Relations of Traumatism of the Peripheral Nerves.—H. N. Moyer offers the following conclusions: (1) Section or laceration of a nerve, if of some size, is usually recognized at the first examination. (2) Contusions of nerves are common, the symptoms often being latent until neuritis develops; the latter may be delayed some days. (3) Contusion of a nerve may complicate any fracture or dislocation, but is especially frequent in dislocations of the shoulder. (4) Injury to the circumflex nerve merits special mention, because of its frequency, the ease with which it is overlooked, and its serious consequences. (5) The "reflex paralysis" after joint injury is probably due to a traumatic neuritis. (6) The management of the joint tendon and muscular complications comprises, in the main, the treatment of traumatic neuritis.

Under What Circumstances Is It Advisable to Remove the Vermiform Appendix When the Abdomen Is Opened for Other Reasons?—From a collective investigation on this topic, and from his own experience, H. A. Kelly is led to emphasize the following points: (1) The appendix should always be examined and its condition noted whenever the abdominal cavity is opened for any reason, provided no additional risk is involved. (2) The opinion of the majority of surgeons in this country is against the removal of a perfectly healthy appendix, 44 to 26 being the proportion shown in his investigation. (3) The opinion of the large majority of surgeons is in favor of removing an appendix which is even slightly adherent to other structures, 60 to 7 being the proportion shown in his investigation. (4) The fact that the appendix is normal in appearance does not prove that it contains no fecal concretions, for he has found them in a number of instances. Their presence is sufficient reason for the removal of an apparently healthy appendix. (5) After removal of the right ovary the stump should always be covered with peritoneum, in order to prevent the risk of adhesion to the appendix. A long and free appendix should invariably be removed.

The Occurrence of Gout in the United States.—T. B. Futcher analyzes thirty-six cases of gout seen in the Johns Hopkins Medical Clinic. He then considers the occurrence of the disease throughout the country and summarizes his views as follows: (1) Gout in the United States is undoubtedly more common than is generally supposed. (2) Out of 13,400 medical cases admitted to Dr. Osler's wards in the Johns Hopkins Hospital during a period of thirteen years, there were thirty-five gout cases, or 0.24 per cent. of the total number of patients. For the same number of years at St. Bartholomew's Hospital there were 116 gout cases out of a total of 31,100 medical admissions, or 0.37 per cent. of the cases. Thus, among hospital patients gout is only about one-third more frequent in London than in Baltimore. (3) All of the thirty-six cases were white males. The largest number of cases occurred in the fifth decade. Twenty-seven of the patients were native-born Americans. (4) The majority of cases appear to have earned rather than inherited their gout. Alcohol and lead seemed to be the most potent predisposing etiological factors. (5) Thirty-three of the thirty-six cases had reached the chronic stage before they came under observation. In seventeen of the cases tophi were present. (6) Among the more interesting complications may be mentioned three cases of gouty bursitis; one case of parotitis; one of pericarditis; one of retrocedent gout, with symptoms simulating intestinal obstruction. (7) There was evidence of disease of the kidneys in the majority of the cases. Albuminuria occurred in twenty-seven, and hyaline and granular casts in twenty-three instances. (8) Arteriosclerosis was present in twenty-three cases, and a mitral systolic murmur in five. (9) Many gout cases are mistaken for rheumatism. Four of the cases were repeatedly diagnosed as such on the early admissions, the appearance of tophi later revealing their true nature. (10) The series illustrates the great importance of examining the ears and the vicinity of the joints for the presence of tophi in all cases of multiple arthritis.

The Medical News, October 25, 1902.

Comparative Toxicity of Ammonium Compounds, a Study in Autointoxication. B. K. Rachford and W. H. Crane in this paper present a table which demonstrates the toxicity of ammonium when combined with most of the ordinary acids which may be found in the body. From the work that has been done on this subject, it may be inferred that ammonium may be an important factor in producing systemic is symptoms in certain acid intoxications. But the importance of the ammonium ions in these intoxications will depend upon the toxicity of the acid ions with which they are combined. The following conclusions are drawn from these experiments: The xanthin bodies are the important toxic principles in the "final fluids," but their toxicity is increased by small quantities of ammonia in combination with them. The quantities of ammonia required to markedly increase the toxicity of these "final fluids" is much too small to give toxicity to any of the inorganic acid ions which have been studied in this paper. In these experiments the amounts of ammonia in a toxic dose of the "final fluids" vary from .0008 to .0003 gram. The toxicity of the "final fluids" is not due alone to the ammonia contained in them, but also to other toxic agents found in migrainous, though not in normal urines, without which the ammonia would have been innocuous. The writer believes that the ammonium compounds of the xanthin bodies give toxicity to the "final fluids," and that these same compounds are toxic agents in producing migraine and other lithæmic disorders, which have been previously described as being due to the xanthin bodies alone.

Note on the Newly-Recognized Sugar-Controlling Function of the Suprarenal Glands.—C. A. Herter calls attention to the importance of the sugar-controlling influence of suprarenal gland in the understanding of the pathology of of human diabetes. A series of experiments were tried on dogs, in which the peritoneal cavity was opened and the suprarenal gland massaged. This manipulation was followed by an increase of sugar in the urine and in the blood. It is probable that an excess of the blood-pressure-raising constituent of the internal secretion of the gland was squeezed into the circulation, and by the action of this constituent on the cells of the pancreas the glycosuria was largely or wholly determined. Removal of the suprarenal glands or ligature of its vessels was followed by a rapid decline in the sugar of the blood. The next experiment described was one in which the suprarenal vessels on one side were ligatured, while on the other side the gland was removed. In a very short time afterward the pancreas was totally extirpated. In every instance the urine, which was previously normal, contained a small quantity of a reducing substance immediately following the operation. But this substance, instead of increasing after the operation, rapidly lessened and left the urine entirely free from any reducing substance. The writer says that one might even suspect that the removal of both pancreas and suprarenals would render pancreatic extirpation inoperative in the production of glycosuria. In his experiments with the effect of the administration of codeine upon the suprarenal gland or its internal secretion, he states that codeine appears capable of rapidly lowering the blood-sugar content of normal dogs.

New York Medical Journal, October 25, 1902.

The Prevention of Smallpox.—M. L. Hughes expresses a firm belief in the efficacy of vaccination, but is not in favor of the use of glycerinized lymph. He advocates isolation, and disinfection with sulphur and formalin gas, and a most rigid quarantine for two weeks. In times of epidemics all should be revaccinated. During convalescence the hair of the patient should be cut close and the scalp thoroughly lathered with carbolic soap. Nothing short of stripping the body before dismissal from the hospital, to review every square inch of skin, and to see and know that all scales have disappeared, will give complete security against further infection.

The Treatment of the Insane in Private Practice.—F. R. Pearce favors the home treatment of many cases of insanity. He says the lesson of acute insanities should be modified and retaught, and the earliest possible treatment instituted; looking toward the cure of the acutely insane in private, long before there is any occasion to think of asylum treatment, valuable as that is in chronic insanity and for the homicidal maniacs and melancholics. Acute insanities of hybrid types, *i. e.* those that savor of two or more types, are the most hopeful in prognosis, and are, therefore, the ones to be kept out of asylums to the last moment. Especially when hysteria enters as an element in the case, the patient should be kept out of an asylum. The physician's duty is to overcome the terror felt by lay folk for the insane, and to engender that hopefulness of treatment of such cases in private which [illegible] general medical affections.

Experimental Gastritis; Early Pathological Changes.—According to F. B. Furch, the following is the sequence of changes in experimental gastritis: (1) The early appearance of an exudate on the surface of the mucosa, composed of cells, granular debris, and fibrillar masses, leucocytes and red cells, within one and two hours after the introduction of the mustard emulsion. (2) Later the debris of cells become more ill-defined, and form a more homogeneous mass. (3) A marked chemotactic effect is shown by the irritant agents employed. (4) The surface epithelium is not destroyed in proportion to the marked changes occurring deeper in the mucosa. (5) There is an early appearance of necrosed acid or parietal cells, which become granular and lose their nucleus. Some cells are found free in the duct, which have the appearance of degenerated acid or parietal cells. (6) Karyokinetic figures make their appearance within six hours, and are very active even deep in the body and fundus of the tubules. (7) Cyst of the glands occurs in twenty-four hours, with accumulation of leucocytes and degenerated epithelial cells. (8) It is important to note that the exudate that forms on the surface at first is not a good soil for the development of microorganisms, but as the exudate becomes changed in character and appearance, bacteria early develop in the coating on the surface. (9) The chemotactic and other effects of irritants evidently are due to peculiar toxic properties.

American Medicine, October 25, 1902.

Arthritis Deformans.—E. H. Bradford concludes that: Arthritis deformans may be regarded as an affection of the organs of locomotion, characterized by a fibrous degeneration of synovial membrane, ligaments, bones, cartilage, and periosteum. This causes an impairment of elasticity, an alteration in shape and stiffness, and is followed by osseous degeneration, bony ankylosis, and irregular bony deposit. The question suggests itself whether these changes are similar in nature to those which produce fibrous degeneration elsewhere, notably arteriosclerosis; and for improvement in our methods of treatment we should look for investigation which will throw light upon the causes of fibrous degeneration and of osseous metamorphosis. What is needed is more complete pathologic reports of the condition of all organs and the whole body in arthritis deformans, through investigations of the changes of tissues in the milder stages of the disease; accurately recorded clinical facts in regard to the arrest of the affection and the apparent self-limitation or long-continued arrest of the disease; careful chemic investigation of the changes of tissues affected; careful examination of the chemistry of the blood in early and late cases of arthritis deformans; careful examination of all the excretions, including those of perspiration and respiration, and thorough metabolism investigations. All this is needed before the disease can be placed upon a satisfactory scientific basis.

Autointoxication in Relation to Mental and Nervous Diseases.—Jay G. Roberts believes that autointoxication is the underlying cause of all cases of neurasthenia. Uric acid itself is not a toxic substance. The manifestations of the so-called uric-acid diathesis are due to the presence of certain products of suboxidation known as the purin or alloxuric bases. These toxic products are the products of the suboxidation of worn-out body materials, and certain articles of food—namely, those containing a large amount of nucleins, such as liver, kidney, sweetbreads, spleen, thymus, etc. These should be carefully excluded from diet of a neurotic patient. The writer concludes his paper with the report of a case of acute confusional insanity, undoubtedly the result of autointoxication from constipation. The patient was a man of fifty two years. There is a marked resemblance between the various sensory manifestations of neurasthenia and those of many infectious diseases. The influence of autointoxication in epilepsy is well known. It is a pronounced factor in migraine. The various neuroses and other nervous psychic manifestations of the menopause may be attributed to this cause. So may the disturbance of pregnancy and the puerperium. Many operation neuroses are probably due to autotoxæmia following sudden inhibition of elimination through fright or the action of anæsthetics. It is a factor in surgical shock. In addition to these disturbances, many cases of temporary mental aberration, unconscious automatism, and acute confusional insanity are due to more or less acute conditions of autointoxication.

The Philadelphia Medical Journal, October 25, 1902.

The Prevalence of Herpes Zoster.—Max Joseph draws the following conclusions: (1) In frequency, herpes zoster causes 1 per cent. of all skin diseases. (2) There appears to be no difference in the occurrence of herpes zoster in men and women. (3) Herpes zoster is a disease of youth (fifteen to thirty years), noted, according to the writer's statistics, in two-thirds of the cases. Before school age the disease is very rare; during school age it becomes more frequent; after thirty years its frequency diminishes, and in old age it is rare. (4) So far as regards the region of the body affected, herpes zoster is, in general, more frequent the more nerves supply the region. There is one exception to this rule, both from the writer's observations and those of Greenough, namely, an exceptionally large number of cases in the trigeminal region. This may, perhaps, be due to the fact that the region supplied by the trigeminus is more open to injury and disease than any other region. (5) Both sides of the body are apparently affected with equal frequency, bilateral herpes zoster being rare. (6) Zimmerleni says that herpes zoster occurs among physicians and nurses in epidemic form; no other occupation seems to predispose to the condition. The final settlement of this point can only be made by consulting industrial and hygienic statistics. (7) Epidemics of herpes zoster occur in the spring and fall. Sporadic cases occur with almost equal regularity throughout the entire year, though some increase is noted in the spring and summer months.

The Value of Diphtheria Antitoxin.—M. Howard Fussell concludes his paper with the following rules: (1) Always make a culture in throat cases; diphtheria cannot be certainly diagnosed without it. (2) When called to see a case of sore throat which is doubtful in character, give antitoxin at once and make the diagnosis by culture afterward. (3) When a case of undoubted diphtheria is seen, administer 2,000 units at once. If there is no improvement in six hours, administer 200 units again. Every twelve hours thereafter administer 2,000 units until improvement begins. (4) Always give a large dose; 2,000 to 4,000 units in the hands of the writer has proven sufficient, but in desperate cases much larger doses may be used, as proven by cases recorded. The writer believes that, given a case of diphtheria in an early stage, it is only a matter of administration of enough antitoxin to effect its cure. If there is delay, even in apparently mild cases, there may develop fatal pathological changes in the organs which will make death or invalidism certain, even though antitoxin be administered later.

A Case of Cretinism Showing the Results of One Year's Treatment.—Alexander Heron Davisson reports this case, in which the signs of rickets and cretinism were very marked. When first seen by the writer, the patient was two years and one month old. Treatment with thyroid extract was begun—one-fourth grain three times a day. A little later the dose was increased to one-half grain three times a day. The next day she suffered with diarrhœa and fever. This may have been a coincidence, but it should be noted that the administration of this drug sometimes causes functional disturbance when first given. It is now more than a year since treatment was begun, and although she still presents undoubted signs of rickets, they are not nearly so marked. The marks of cretinism are also much less apparent. She has gained seven and one-half pounds and has grown three and one-quarter inches in height. She has cut eighteen teeth, and the circumference of both chest and head is one inch greater. The expression is bright and cheerful Twelve grains of thyroid extract are now being taken daily.

The Lancet, October 18, 1902.

Notes on an Outbreak of Septic Sore Throat Caused by Milk.—W. G. Nash reports a series of cases of sore throat without special features. Investigation showed that all the families of the patients were supplied by the same dairyman. In some of the families who boiled their milk no cases occurred, though the milk came from the same source. Examination of the dairy showed no cause of contamination. Cultures from the throats showed only staphylococci and short streptococci.

Double Oophorectomy in Mammary Carcinoma.—Notes of a case are given by L. McGavin, whose patient was a woman of forty-two years. Two years before admission to hospital the left breast and axillary contents had been removed. On admission, seven small, hard nodules were present in the skin of the scar line, also one nodule in the axilla as large as a walnut. Little pain and tenderness were felt. There was no œdema of the arm, nor any enlargement of the supraclavicular glands. Both ovaries were removed and found healthy. Relief was but temporary, and at the time of the report there were symptoms suggesting secondary deposits in the upper dorsal spine and left lung. The chief points of interest in the case are as follows: The patient had not reached the climacteric, and was, therefore, presumably a case favorable for treatment by oophorectomy. The periods ceased at once, proving that the primary object, at least, had been attained. In spite of this, the result was a complete failure to arrest the progress of the disease so far as the breast area was concerned; the mass in the axilla, however, gradually disappeared, and cannot at the present time be felt. It has in no way affected the arm, which is at present free from œdema. This disappearance I imagine to be due to interference with the blood-supply rather than to any trophic influence exerted by the artificial menopause.

Notes on a New System of Treatment in Pulmonary Tuberculosis.—D. Turner advocates the employment of "oil massage," his mixture consisting of four drachms of creosote or guaiacol, one drachm of oil of citronelle (to disguise the smell of the other ingredients), and cod liver oil to make four ounces. At his sanatorium the application of the oil massage is made daily. The patient, after being hardened by repeated cold spongings for two or three days, lies on a couch, all clothing being removed. Then the body is sponged with a weak solution of bicarbonate of soda (one drachm in a pint of water) and dried with a soft towel. The oil mixture is then rubbed in all over the trunk from the neck to the pelvis, back and front, the quantity used at a time being from one to two tablespoonfuls, according to size and age. In cold weather a small blanket serves to keep the body partially covered. The process occupies a quarter of an hour, and its efficacy depends very much on the vigor of the operator; if only carelessly smeared on without being rubbed in, very little benefit will ensue. Over the abdomen some kneading is done in addition to the rubbing. When galvanism is used, generally only one pole is applied over the solar plexus, and the other is moved up and down over the upper part of the spine. If the patient is feverish, the temperature generally falls a degree or more after every rubbing, the cough is easier, the appetite improves, and the night sweats cease; there is a general feeling of well-being, and the improvement in the lung goes on *pari passu* with the gain of weight. In private practice, if the patient is following any vocation, pure olive oil is used. Oil massage is not recommended in advanced cases or in those inclined to hæmoptysis. Results in children are better than in adults.

The Treatment of Atonic Dilatation of the Stomach by Means of High-Frequency Currents.—Personal experience with seventeen cases forms the basis of the remarks of A. Crombie and T. J. Bokenham. The apparatus employed consisted of a Ruhmkorff coil, giving a twelve-inch spark with heavy discharge. The secondary wires of the coil are led to the inner coats of two Leyden jars with adjustable dischargers. The outer coats of the jars are connected through a variable number of turns of thick wire, one of which is connected with the earth, the other with the lower coils of an Oudin's resonator. The current used for treatment is obtained from one of the upper coils of the resonator, and it is a rapidly surging, alternating current of high voltage. It is applied in a variety of ways, by special electrodes, *e. g.* monopolar brush, glass or ebonite condensers, and moistened flexible plates of sheet lead, and of large size. In the early cases treated the patient was placed on a couch and the region of the stomach was "sprayed" by a brush electrode held at a distance just beyond that at which a direct spark would pass between the electrode and the skin. The effect experienced was described as similar to the dropping of a shower of warm sand on to the skin, and after a few minutes peristaltic movements of the stomach would often be distinctly felt. A very convenient condenser electrode can be made by filling a large flat-bottomed flask with salt water and passing a wire through an indiarubber cork fitted to its neck, the free end of the wire being connected to the resonator. With such an arrangement the effect is, perhaps, more exactly localized to the region it is desired to influence. The lead foil electrode is of such a size as to cover the whole gastric area; close contact is secured by interposing a layer of wet flannel between the metal and the skin. With this the patient usually feels scarcely anything over the area of application, and the quantity of the charge depends upon the electrostatic capacity of the individual. The effect of the application is in most cases highly invigorating. After a number of applications the stomach was found to have assumed its normal position and size, and the other parts of the intestinal tract to have returned to their normal relative positions. In all but two cases normal digestion was restored. In one there was no improvement in digestion, owing, apparently, to hypochloridia, although the stomach remained of normal size.

Deutsche medicinische Wochenschrift, October 2, 1902.

Inoculation Tuberculosis.—O. Lassar has collected a series of figures which show that the relations between bovine and human tuberculosis are closer than is thought by many. Ten cases of inoculation tuberculosis were observed among 365 persons employed in some capacity in the handling of cattle. Among persons engaged in other avocations inoculation tuberculosis is very rare, constituting only one-third of one per cent of all cases of tuberculosis. These, together with many observations of other authors, make it clear that man is very far from being insusceptible to bovine tuberculosis.

Chronic Diphtheria.—Ernst Neisser reports an instance where a case of chronic diphtheria in a nurse girl gave rise to two cases of the acute form of this disease in the children which were intrusted to her care. This girl had suffered from a chronic throat affection for several years, which dated from an attack of diphtheria in her brother, whom she nursed. Her clinical history was similar to that which has been described by the author as characteristic of chronic diphtheria, and consisted essentially of a series of attacks of sore throat attended by few or no constitutional symptoms. A culture from the throat revealed the presence of virulent diphtheria bacilli; although submitted to energetic treatment, the bacilli remained in the throat. The blood of the patient was tested for the presence of antitoxin, and it was found by computation that in her entire blood there were approximately 2,000 antitoxin units. We here have an instance in which virulent diphtheria bacilli were constantly present in the throat of a person who possessed a high degree of immunity, and in whom the clinical symptoms were periodical and trivial.

Berliner klinische Wochenschrift, October 6, 1902.

Acroparæsthesias Following Traumatism. Max Sommer reports a case of this rare condition. The paræsthesia first developed three or four months after an injury to the left hand, and at a time when the wound had entirely healed. The symptoms consisted of a feeling of numbness in the hand, which was periodical in appearance. At times distinct pain was present. Combined with these there was a stiffness of the involved parts, and a sensation as if they were swollen. The symptoms were principally present during the day, but occasionally appeared during the night. Treatment was entirely without benefit.

Unity of Streptococci.—Fritz Meyer, as the result of extended experimental observations, agrees with Marmoreck in his stand against the unity of streptococci. Meyer has examined streptococci obtained from the following sources: tuberculosis, measles, erysipelas, scarlet fever, abscesses, phlegmons, puerperal septicæmia, follicular angina, rheumatic angina, ulcerative endocarditis, and the lymphatic glands of horses. The organisms thus obtained differ in morphology, virulence, hæmolytic and minimizing properties, and fail to grow in their own culture filtrates, but grow readily in heterogenous filtrates. The greatest difference in morphology was encountered, including chains of various lengths. According to the species, the individual organisms were of biscuit-shaped, round, or elongated form. The ability to increase the virulence by either cultural growth or animal transmission was also varied. One of the most forcible arguments against the unity of the streptococci relates to their intergrowth in culture filtrates of the various species as originally shown by Marmoreck. Meyer confirms these results in all particulars. Immune serum obtained by inoculation of one variety is totally unable to protect animals inoculated with another variety, although it is fully active against infection caused by its own inoculation. All of these facts demonstrate beyond the peradventure of a doubt that the microorganisms now included under the class name of streptococci include a number of distinct species.

Münchener medicinische Wochenschrift, October 7, 1902.

Gonorrhœal Urticaria.—Orlipski reports a case of this rare form of urticaria. The patient, a male, had experienced two attacks of gonorrhœa, both of which were accompanied by an urticaria which was more or less diffused over the whole body. The usual remedies possessed no action upon the eruption. In both attacks the eruption vanished with the cessation of the gonorrhœa. The patient had never suffered from any eruption when free from the gonorrhœa. The urticaria did not show any peculiar characteristics which could distinguish it from the ordinary forms of that disease.

Operative Treatment of Certain Lung Diseases.—G. Treupel reports a case of non-tuberculous circumscribed consolidation of the left lower lobe, which was operated upon with favorable result. The patient, a child, had suffered with periodical cough and purulent expectoration for several years. The general condition was good. Physical examination showed a circumscribed area of dulness in the location above noted. Careful microscopical examination failed to reveal the presence of tubercle bacilli in the sputum. The ribs were resected over the involved region, and a lung fistula established, through which a purulent discharge was evacuated. Following this the attacks of coughing became very much less frequent and the purulent expectoration entirely ceased The fistula remained open for about seven weeks. The expectoration has not returned since its closure a period of about three months.

Nervous Irradiations in the Region of the Urinary Organs.—Willi Hirt considers the diagnostic value of radiating pains, contractions, and vasomotor appearances in the region of the urinary organs. Many authors have recorded the fact that various surgical procedures, intestinal irritations, and peritoneal inflammations are frequently attended by disturbances of urination, especially retention. In a like manner, various disturbances of the urinary tract may give rise to radiating pains or muscular contractions in other structures. One of the most important of these phenomena from a diagnostic standpoint, is the contraction of the abdominal muscles, since this occurs in many cases of ureter and kidney disease. Such contractions may be unilateral or bilateral When present in cases of abdominal injuries they indicate a severe lesion of the kidneys or ureters, and demonstrate that operative procedures are necessary. There also frequently accompany purulent processes in these tissues. Here they are usually unilateral and are of great diagnostic importance. Especially important are the irradiations which proceed from one kidney to the other in cases of unilateral kidney affection. Among these is included the so-called reflective anuria. In such kidney affections, however, the irradiations are not confined to the sound kidney, but may be present in other portions of the urinary tract. This is particularly apparent in renal tuberculosis, in which disturbances of the ureter, bladder, and urethra are often present and are generally to be regarded as nervous in character. In all cases of kidney affections which show accompanying disturbances along the urinary tract great care should be taken in the treatment of the latter, since careful diagnostic measures may show that such are not caused by any anatomical lesions, but are simply radiations from the diseased kidneys.

Russki Arkhiv Patologii, etc., August 31, 1902.

A Contribution to the Study of the Formation of the Specific Precipitins of Kraus.—B. Belyayev records his experiments with the serum of typhoid patients and that of animals immunized with Eberth's bacillus, conducted with the object of studying the agglutination of the microbes in connection with the phenomenon of precipitation of Kraus. He found that: (1) A high agglutinating power of the serum does not always cause the formation of the precipitins; (2) The agglutinating power of the serum is not diminished after the formation of the precipitins; (3) Longer immunization of the animal is required for the obtaining of the precipitins than for the agglutination. The author concludes that the two phenomena are entirely independent of each other.

Gastric Digestion in Hanot's Disease.—N. Kirikov, in his experimentations, has not found that in hypertrophic cirrhosis with chronic icterus (Hanot's type) hyperpeptic gastritis is always present Rather is there hypopepsia, and even the absence of free hydrochloric acid in the stomach contents. The variations in the gastric contents do not depend upon the icterus alone, but also on the degree and intensity of the causal disease, and the oscillations in the general condition of the organism. The anatomical and functional condition of the cells of the gastric mucous membrane have also an important influence. It is probable that the bile circulating in the tissues has a stimulating influence on the nerve endings of the pneumogastric and on its centers. Hyperchlorhydria in Hanot's disease does not always coincide with hyperpepsia.

Experiments for the Transformation of Non-virulent Diphtheria Bacilli and Pseudodiphtheria Bacilli into Virulent Diphtheria Bacilli.—M. Bomstein says that a study of the literature of the subject shows that there are diphtheria bacilli of different degrees of virulence, and even diphtheria bacilli which have completely lost their virulence and yet have preserved all their morphological and physiological features. The best method for the reinforcement of the virulence of a microbe consists in cultivating the bacteria in collodion introduced into the peritoneum of an animal. By this means the author has transformed inoffensive bacilli into virulent bacilli, and has even obtained a diphtheria toxin which was capable of being neutralized by the antitoxic serum. Experiments conducted in the same manner with the pseudodiphtheria bacillus were a complete failure.

Society Reports.

THE NEW YORK STATE MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, Held in New York City, October 20–23, 1902.

Alvin A. Hubbell, M.D., of Buffalo, President.

(Concluded.)

FOURTH DAY—THURSDAY, OCTOBER 23.

The Advantages of Nitrous Oxide in General Surgery Exhibition and Description of a Stopcock for Its Administration with Varying Percentages of Oxygen.—Dr. H. W. Carter of New York City read this paper and exhibited the apparatus. He said that all food should be withheld for three or four hours before the administration of nitrous oxide. The patient should be shown how to breathe before beginning the administration of the gas, and care should be taken that the face-piece is accurately applied. The gas should be administered as nearly as possible at the atmospheric pressure. The drawing of the gas from the bag through a long tube often gave rise to a suffocative sensation, and under these circumstances stertor was more apt to supervene much earlier and the anæsthesia to be of much shorter duration. The use of the long tube was not so objectionable when the gas was taken from a gasometer under a positive pressure. After beginning the administration of the gas great care should be taken to avoid loud talking or anything else which might disturb the patient. The occurrence of anæsthesia was indicated by stertor, altered color, widely dilated pupils, and diminished or absent conjunctival reflex. Nitrous oxide, anæsthesia would be found useful in connection with painful dressings or the performance of various minor surgical operations, such as dilatation of the sphincter ani, dilatation of the cervix uteri, the opening of abscesses, the breaking up of adhesions in joints, etc.—indeed, in a large class of operations occupying from a few minutes to half an hour. In connection with the paper Dr. Carter exhibited an improved stopcock that he had devised, and which was so constructed that, if desired, it could be used in connection with Bennett's apparatus. It was important to properly arrange the posture of the patient before beginning the lengthy administration of nitrous oxide and oxygen. No other form of anæsthesia required such skill and unceasing vigilance on the part of the anæsthetist. The longer the administration, the larger the proportion of oxygen required. At first the patient breathes only air, then pure nitrous oxide gas for a few inhalations, after which the oxygen is admitted and the percentage is steadily increased at intervals of a few inhalations. If the patient became excited, or began to sing, cry or talk, or the color of the face assumed a bright red, no further oxygen should be admitted, or the percentage of this gas should be reduced for a moment. The rapid and pleasant induction of narcosis and complete recovery, and the almost entire freedom from vomiting and other unpleasant after effects more than counterbalanced for the expense of the method, the difficulty of administration, and the cumbersomeness of the apparatus.

Dr. Alvin A. Hubbell of Buffalo remarked that in his city they had been using a combination of ether and nitrous oxide, a method which was, of course, not entirely new. It had been found in some of the hospitals there to be a very safe and efficient method of inducing anæthesia.

Suggestions Favoring a Standard Technique in Operative Surgery.—Dr. Edward Wallace Lee of New York City presented this paper. He thought that surgery had made sufficient advances to warrant calling a halt and a careful sifting of existing methods, The frequent changes in technique and the great differences of opinion on this subject not only caused confusion and tended to consign certain methods to unmerited oblivion, but such a chaotic state did not tend to inspire confidence on the part of the laity. He thought we should be content to have fewer masters and more followers. Surgical technique should be standardized by a surgical congress, whose membership should be made up of eminent surgeons recognized as leaders in that art.

Dr. A. J. Ochsner of Chicago said that if a surgeon had a foolish idea with regard to some particular operation, and it was harmful, it would certainly be eliminated, whereas if it were harmless it would be allowed to remain. This would eventually result in far greater uniformity in surgical technique. It should not be forgotten that in China about four thousand years ago the people thought they had arrived at the point where everything was done in the best possible way, and consequently ever since then they had continued to do everything that way.

Dr. William J. Mayo of Rochester, Minn., said that he found it impossible to feel, as did the author of the paper, that he had reached the point where he could not improve, and he was free to confess that he looked forward with pleasure to seeing the young surgeons do things in a different and perhaps better way.

Dr. J. J. Walsh said that medical history was full of the effort of the older men to establish a standard against which the younger men should do nothing. It would be nice to have a standard, but art is long and time is fleeting; moreover, medicine is not a science but an art, and must, therefore, allow the pendulum to swing a little here and there.

Dr. Lee, in closing the discussion, explained that he was far from being opposed to progress, but students were necessarily confused when one progressor extolled one method, and, an hour later, in the same room his confrère condemned this same method. It was particularly necessary that the men who only do surgical work occasionally should have fixed ideas as to what should be done.

Points in the Control of Emergency Hemorrhage, Both Medical and Surgical.—Dr. Robert H. M. Dawbarn of New York City was the author of this paper. He said that hæmoptysis and cerebral apoplexy were typical of what was meant in the paper by the term medical hemorrhage. The late Dr. A. L. Loomis used to say that ergot, galic acid, and similar drugs were of no use in hæmopytysis, and that the only useful drugs here were morphine, to allay nervous excitement, and, perhaps, aconite to reduce the blood pressure. In the present paper he desired to recommend the treatment of such hemorrhage by controlling the circulation in three of the extremities by means of a towel or "Spanish windlass." The towel or handkerchief should be loosely knotted around the limb at the junction with the body, and then tightened by twisting with a stick until the venous return is checked, as shown by the swelling of the limb. One should, however, avoid stopping the pulse on the distal side of the windlass, the limbs should be watched and kept well warmed, and after two or three hours the circulation should be allowed to slowly return. To avoid injury to the limbs, they may be bandaged in turn for shorter periods, thus keeping a considerable portion of the blood of the body sequestered for a sufficient length of time to allow of clotting at the seat of the hemorrhage. This method was applicable, of course, to both hæmoptysis and apoplexy—indeed, to any kind of hemorrhage of a dangerous character in an inaccessible part. The older physician sought to accomplish the same thing by bleeding, but after the original hemorrhage had ceased the patient would want this blood; hence, the advantage of the plan to bleed the patient temporarily into his own vessels. In cases of apoplexy this lowering of the blood pressure often resulted in checking the formation of clot.

Treatment of Epistaxis.—Speaking of surgical hemorrhage, Dr. Dawbarn referred to the treatment of epistaxis. Where the bleeding point could be seen, it might be cauterized in an emergency by heating a hair-pin. It was also worth while trying an application of a 10-per-cent. solution of ordinary kitchen gelatin in water. In plugging the nostrils, or, indeed, in tamponing for hemorrhage elsewhere, it was important not to use *absorbent* cotton or gauze. Sterilized cotton batting was far better. After the introduction of a double string into the nose by means of a soft catheter, the middle of this double string, hanging out of the mouth, should be tied to a ball of cotton batting, and the latter pulled tightly into the posterior nares. This operation would be facilitated by holding the soft palate out of the way with a bent tablespoon. Making strong traction on the two ends of the string coming out of the nose, the bleeding side of the nose is filled with saline solution. This "water seal" tends to check the hemorrhage and, at the same time, demonstrates to the operator whether or not the posterior tampon is sufficiently tight. Moreover, this fluid prevents the formation of a huge blood clot in the nose. Having proved the effectiveness of the posterior tampon, the anterior tampon is tightly tied, and the tampons are left in place for about twenty-four hours. They are removed by a reversal of the procedure just described.

Dr. F. W. **Higgins** of Cortland said that he had found the oil of origeron a useful remedy in the treatment of hemorrhage. A small bandage folded squarely and put into the nose, and then pressed from the outside, would, he believed, control any case of nasal hemorrhage, and he had seen some very severe ones. Most nasal hemorrhages came from a spot situated about one-third of an inch from the nostril. If from this situation, the hemorrhage could often be controlled by pressure with the finger.

Dr. **Homer Wakefield** of New York City said that the inhalation of pure nascent oxygen gas in internal hemorrhages had been the nearest to a specific of anything he had tried. He believed the oil of origeron acted as an oxygen-carrier in the blood, for it was known that all terpenes absorbed oxygen, and that if they had already absorbed oxygen before being used, they lost their property of controlling hemorrhage. In all internal hemorrhages it was a very valuable drug, especially where there was marked anæmia and a decided reduction of the hæmoglobin.

A New Treatment for Hæmophilia.—Dr. A. J. **Ochsner** of Chicago referred to a method of treatment in cases of hæmophilia, which had not been published. It consisted in giving albumin in the form of the whites of eggs. When from four to six whites of eggs were given, three times daily, there seemed to be a very definite effect exerted upon the blood of these persons. He added that Mayo Robson had prescribed drachm doses of chemically pure chloride of calcium, largely diluted, three times daily, or as an enema, every four hours for four days, in cases of hemorrhages accompanying cholæmia.

Dr. **William** J. **Mayo** of Rochester, Minn., said that, as hæmophiliacs were often encountered quite unexpectedly in the course of operative work, it was well to learn everything of value that was known with regard to the management of these very troublesome cases. He knew that cases of cholæmia showing purpuric spots on the skin invariably died from hemorrhage if operated upon He bad tried the chloride of calcium treatment in cholæmic cases, and since he had adopted this treatment he had not seen any severe hemorrhages, although he would admit that he was very careful about operating on the purpuric cases. The speaker said that while preparing to tampon the nose for hemorrhage it was well to instruct the patient to hold the nose tightly with the fingers, for often, by the time the surgeon was ready to insert the tampon, the bleeding would have been checked. It was the passage of air through the nose that broke up the clot and caused the bleeding to persist.

Symposium on Pneumonia.—This comprised the following papers:

Pneumonia from the Bacteriological Standpoint.—Dr. A. C. **Abbott** of Philadelphia presented this, the opening paper of the symposium. He said that the striking clinical peculiarities of pneumonia were its occasional epidemic nature and its peculiar mode of termination, and that these had long ago aroused a suspicion that the disease should be looked upon as a typical infection Up to 1883 no effort had been made to cultivate the microorganisms from the lung in pneumonia. It was at this time that Friedlander described his diploccocus. At the present time, however, very few still accepted Friedlander's original views as to its significance. In 1884 A. Fraenkel succeeded in isolating in pure culture from a case of pneumonia the organism known as the micrococcus lanceolatus At the same time the close relationship between this organism and the diplococcus found in saliva in 1881 by Sternberg and Pasteur was first recognized. The work of Wechselbaum in confirmation of the nature and significance of Friedlander's diplococcus was of great importance, not only because of its scientific precision, but because it was founded on a most careful and exhaustive study of 129 cases. The more recent researches of numerous excellent observers afforded good ground for being doubtful of the pathological significance of the Friedlander diplococcus, and of the close relation between pneumonia and the micrococcus lanceolatus It was true that bacteriological proof of this being the cause of pneumonia was not perfect, but there were many difficulties in the way of producing pneumonia experimentally in animals. There was, nevertheless, conclusive proof that this diplococcus does produce spreading inflammatory exudates having all the characteristics of the exudate of acute pneumonia in man. From the fact that the pneumococcus was commonly found in the mouth, it was probable that infection from this source usually took place through the upper air passages, or the accessory sinuses, but there was some evidence pointing to the intestine as an occasional point of entrance. While there was but little doubt as to the toxæmia produced by the pneumococcus in its growth, there was as yet no evidence that there was any relation between the virulence of this organism and the production of toxin.

Dr. **Alexander Lambert** said that he had made experiments in his hospital practice with antipneumococcus serum, using it on thirteen patients, but, so far as he could judge, with practically negative results. The lungs being, so to speak, outside of the blood vessels, the serum does not reach the exudate, where it was most needed. In a certain number of the cases, the serum seemed to prevent the general septicæmia which is observed in fatal cases. In one man, having a pneumococcus septicæmia, the serum controlled this, the pneumonia running a normal course thereafter and terminating in recovery. The non-diffusibility of the immune body was a great disadvantage. It belonged to the globulin type, and was not a nucleoalbumin.

Leucocytosis in Pneumonia. Dr. **Alexander Lambert** of New York City read this paper. He said that for a number of years this had been a favorite field for investigation. Leucocytosis appeared either simultaneously with the chill, or a very few hours afterward. It was now generally acknowledged that the intensity of the leucocytosis was not always in proportion to the intensity of the symptoms, but followed the same line which governs leucocytosis in other diseases. While it varied considerably with the amount of lung tissue involved, it did not always run evenly with the amount of exudate. Good resistance and mild infection would show small leucocytosis, but with good resistance and intense infection the leucocytosis would reach the maximum. Hence, the leucocytosis alone was of no value in prognosis. In general it could be said that mild cases would show from 6,000 to 12,000 in a cubic millimeter, and in very severe cases, 30,000 to 50,000. When one lobe was involved, the average was 20,000; with two lobes, 22,700; and with three lobes, 25,000. If the temperature fell by lysis, the leucocytes diminished gradually and often reached the normal when the temperature reached this point. To be of any great assistance as routine matter of diagnosis, the leucocytosis must be determined almost daily, a fact which practically excluded.

this method from the daily work of the general practitioner. The polymorphonuclear cells formed eighty to ninety per cent; the large mononuclear cells were usually present in considerable numbers, and were often decreased, though never entirely absent. During defervescence, the polymorphonuclear cells rapidly diminish to normal, and the mononuclear cells become more abundent. The speaker then referred to a hospital study that he had made of leucocytosis in eighty-seven cases of acute lobular pneumonia. In this study, it was found that a persistently subnormal leucocyte count, that is, below 7,000, almost invariably pointed to a fatal termination When resolution was delayed, even though the temperature was nearly normal, the leucocytosis did not disappear until the lung was free from exudate. The most puzzling factor in considering the leucocytosis was the tremendous variations which occurred in it. One of the common occurrences of pneumonia was a further extension of the disease either in the same lung, or in the other lung. This was associated with an increased leucocytosis. When a large surface of lung was resolving, there was a marked increase in the leucocytosis. According to his personal experience, empyema developed as a complication, rather than as a sequel, of pneumonia. When it occurred, the doubling of the leucocyte count was very striking.

Treatment of Pneumonia.—Dr. Joseph W. Grosvenor of Buffalo contributed this paper, but, owing to lack of time, only the conclusions were read. They were as follows: Without doubt a mild case of pneumonia would recover without medicinal treatment. Blood-letting as a remedial agent in pneumonia was inadmissible except in rare cases, occurring in very robust persons with marked cyanosis and extremely difficult breathing. So-called abortions of pneumonia were usually abortions of colds. At the onset, the physician should recognize the toxæmia as the main factor in the maintenance of the disease. This was to be combated by elimination of the toxins and increasing the vital resistance. Oxygen should be more generally recognized as an efficient remedy in the last stage of pneumonia. The danger resulting from cardiac depression should be kept in mind, and stimulation begun early. Alcohol, being a cardiac depressant, was not useful in heart failure. Serum therapy, as applied to pneumonia, was still in the experimental stage. The author's concluding advice was: "Treat not only the disease but the patient; Nature is a first-class physician."

The Finsen Light Treatment of Smallpox; Also the Finsen Light Treatment of Various Dermatoses by Concentrated Chemical Rays, with Exhibition of the Lamp.—Dr. Francis P. Kinnicutt of New York City presented this communication. He said that the treatment of smallpox by Finsen consisted in keeping the patient in a room in which the blue, violet and ultra-violet rays of light were excluded by the interposition of red glass or red cloth. The object was to prevent or cut short the stage of suppuration. The treatment must be continued without any interruption until the vessicles have all dried up. It should be commenced as soon as possible after the appearance of the rash, for the nearer the suppurative stage the treatment was begun the poorer the results. Finsen claimed that if the treatment were faithfully carried out in all its details, the patients would usually recover without suppuration and without scarring. Since 1894 the treatment had been carried out by many physicians both in institutions and in private practice, with results comparing very favorably with those claimed by Finsen himself.

Concerning the therapeutic effects of concentrated chemical rays, the speaker said that tuberculosis was a dermatosis which was especially favorable for a study of this subject. At the Finsen Institute, of 456 cases in which the treatment had been completed at the end of 1900. 130 were free from recurrence at the end of periods of from one to five years. Of forty-nine cases of alopecia areata a cure was obtained in thirty. Of twenty-five cases of acne vulgaris which had resisted ordinary therapeutic measures, thirteen were cured. Dr. Kinnicutt presented a lamp similar to those used in the London hospitals It allowed of an electric arc's being used close to the patient's skin. The body of the lantern formed a water jacket, and through the latter cold water was kept constantly circulating, thereby preventing the heat rays from reaching the skin. The lamp was readily adjustable, the parts were all open for inspection and management, and the instrument could be readily sterilized. This lamp required ten amperes with the continuous current and sixteen with the alternating current, and about forty-five volts with either form of current. The lens of the lamp is placed directly in contact with the diseased area, and the parts are exsanguinated by the pressure of the lens on the skin. This is done because the blood is found to be the largest absorbent of the chemical rays of any tissue of the body. The application was usually continued for fifteen minutes. The technique of the treatment was simple, and no constitutional reaction was ever noted. The speaker said that he thought it was generally recognized to-day that this treatment with concentrated chemical rays was a new and valuable therapeutic resource. This apparatus was now in use at the Presbyterian Hospital of this city. Those who had tried both the *x*-ray and the Finsen treatment in lupus vulgaris were of the opinion that the latter was better. The lamp was then exhibited in action, as was also a case of lupus erythematosus which was now undergoing the Finsen treatment.

Dr. W. S. Gottheil said that the criticism that he would make of this apparatus was that it was not sufficiently powerful, thus requiring unnecessarily prolonged exposures. His own apparatus, one made in this city, made use of sixty amperes of current. Out of the last four cases treated, three were entirely cured in sessions varying from six to fifteen in number. Lupus vulgaris and tuberculosis cutis were positively curable by this means. It had been proved that a sufficiently intense light of this kind would penetrate the entire body, for he had in his possession photographs taken by the light which had passed completely through the body of a stout man.

Dr. Milton Franklin of New York City declared that any light apparatus of this kind in which the light was permitted to pass through glass was inefficient, because at the present time there was not in the market any kind of glass which would permit the ultra-violet rays to pass through it. Experiments were in progress looking to the manufacture of a kind of glass that would allow of the passage of these rays, but, so far, the only crystalline substances tranparent to these rays is rock crystal.

Dr. L. Duncan Bulkley said that he had recently come from a visit to the Finsen Institute at Copenhagen. An enormous number of patients were being treated there, and certainly the results of treatment of lupus vulgaris were remarkable. However, the treatment was exceedingly slow, some of the patients having had between 300 and 500 sittings of one hour each. That the treatment was thoroughly efficacious was shown by the fact that some of these patients had been well for two or three years. It was rare for even the most favorable cases to be cured in twenty sittings. It was only fair to say that the treatment at the Finsen Institute embraced many other things besides the Finsen light. After each treatment with the light the patients receive applications of various ointments, and are sometimes even curetted; hence he did not believe the same results could be obtained from this light treatment alone Some burning resulted in almost every case, and when it occurred the affected part was not subjected to the light treatment for about one week. All cases were photographed at the commencement of the treatment, and from time to time afterward. Although at the beginning this treatment was employed in connection with sunlight, the electric light had been exclusively employed for the past two years.

The Rontgen Ray; Its Mechanics, Physics, Physiology, and Pathology.—Dr. Eden V. Delphey of New York City presented this paper. The different forms of the more important apparatus employed in connection with the use of the Röntgen ray were described, as well as some of the physical laws governing the action of this ray. Regarding *x*-ray burns it was stated that they do not occur except after an exposure equivalent to at least five minutes at a distance of ten inches. The bactericidal effect of the Röntgen ray, according to this author, was insignificant. The changes in blood vessels were very marked, and probably largely explained the therapeutic effects of these rays.

The Operative Treatment of Fractures as Indicated by the Röntgen Rays.—Dr. Carl Beck of New York City presented this paper. He said he had embraced every opportunity to emphasize the sense of security which the surgeon now enjoys in the treatment of fractures under the mentorship of the Röntgen ray. Radiographs were then presented to illustrate the forms of fracture, and brief remarks were made on the methods of treating them.

Results in Fifty Cases of Cancer Treated with the Aid of the Röntgen Rays.—Dr. Charles Warrenne Allen of New York City was the author of this paper. He said that laboratory experiment had shown that the Röntgen ray is a reducing agent. He thought that, aside from personal idiosyncrasy and the greater possibiliy of burning by the non-penetrating rays, there was a condition of tube and a degree of heat color in the anticathode which made a particular tube at a particular time likely to produce the so-called burn. Furthermore, the ray undoubtedly had a predilection for tissues of embryonic structure, or those not strongly differentiated or highly individualized, and, if the expression might be permitted, on "cells out of place." The fifty consecutive cases forming the basis of this paper ranged in age between fifteen and eighty years. Twenty-two of them were males. There were thirty-three cases of epithelioma of the rodent ulcer type, and ten cases were cancers of the breast, seven of them recurrent. Only 8 per cent. were unimproved; 20 per cent. were improved but were still under treatment; twenty-six cases, or 52 per cent., had been discharged as cured. His conclusions were: (1) The *x*-ray possesses decided therapeutic power; (2) it may produce decided injurious effects aside from the so-called burn; (3) symptoms referable to the systemic effects may arise from the direct action of the ray, or indirectly by absorption of products of disintegration, which seemed at times to be thrown into the circulation more rapidly than they can be eliminated from the system; (4) carcinoma may develop in scar tissues following an *x*-ray burn; (5) the method is not to be used in all forms of cancer, and the indiscriminate use of this potent remedy should be discouraged; (6) by the proper use of shields dermatitis may usually be entirely avoided, and (7) the improvement under this treatment is better than can be effected at the present day by any other known method.

The Röntgen Ray in Gynecology.—Dr. Eden V. Delphey presented this paper also. He said that the *x*-ray picture of the pelvis was often very indistinct and unsatisfactory, and would rarely afford much assistance to the gynecologist, who had already become expert in the palpation of this region. Somewhat better results were obtained above the pelvic bones, as, for example, in connection with the ureters and kidneys, but the Röntgen ray could render little assistance to the trained touch of the abdominal surgeon. The chief use of the Röntgen ray in gynecology was in connection with new growths in the pelvis. Good results had been reported from the *x*-ray treatment of carcinoma of the uterus. It should not be forgotten that even in some of the cases that had resulted favorably no improvement had been noted for a considerable time after beginning the treatment.

The Rontgen Ray in Obstetrics.—Dr. Joseph B. Cook of New York City read this paper. He said that it was true that the pelvis of the non-pregnant woman could be studied by one skilled in the use of the *x* ray, but many inaccuracies arose from the distortion of the shadow, and when to this difficulty were added the difficulties arising during pregnancy from the interposition of the fœtus and other factors, the results could not admit of comparison with those obtained by the usual pelvic examination made by a skilled obstetrician. The maternal pelvis could be clearly seen up to four and a half months in pregnancy, but after this the uterus and its contents formed a veil on the negative. It was claimed to be possible to determine by the Röntgen ray examination the position and presentation of the child, and the degree of flexion near the termination of pregnancy. The speaker thought the *x*-ray might prove of possible and distinctive value in cases of multiple pregnancy.

Dr. William James Morton presented the Kjaldsen lamp in order to show how the expensive and complicated apparatus of Finsen could be simplified. It had been found, he said, that simple iron electrodes, used as an arc instead of carbon, gave a light extremely rich in ultraviolet rays. The lamp was small, portable, and comparatively inexpensive. He could not agree with Dr. Allen that *x*-ray burns were dependent upon idiosyncrasy in the usual acceptation of that term. Dr. Allen's results were excellent, yet he thought there should be 100 per cent. of successes in the *x*-ray treatment of rodent ulcer. He had personally treated a large number of cases of primary carcinoma of the breast, and in this particular field he objected to the use of screens and specula, for he had no desire to screen off the action of the *x*-ray, but, on the contrary, endeavored to secure its wide application.

Dr. William B. Coley of New York City was of the opinion that the *x*-ray would prove of service as an adjuvant rather than as a substitute for operation in cases of cancer, though in this statement he did not refer to the superficial forms, such as rodent ulcer. Since February, sixty-eight cases of cancer had been treated at the General Memorial Hospital, twenty-five cases being sarcoma and seventeen recurrent carcinoma of the breast. They could not be reported as cured at this time simply because they had disappeared under the *x*-ray treatment. For example, one case that had been reported by another physician as a probable cure had recurred in the lung, and had caused death about three months later. His experience had been that many of these cases recur in a short time. The greatest future of this treatment seemed to be as a prophylactic agent used immediately after every operation for primary carcinoma.

Very Dangerous Symptoms Following a Tarantula Bite.—J. S. Boyers reports the case of a man who was bitten on the right index finger while pulling bananas from a banana stock. In about two minutes he was in a dazed condition. The author made a crucial incision to the bone, held the finger under the hydrant, rubbing it with running water for about a minute, and applied a saturated solution of potassium permanganate. The pulse could scarcely be felt at the wrist; there was a spasmodic difficulty of breathing, in which the muscles of respiration seemed almost completely paralyzed, lasting from one to two minutes and returning in ten minutes at first. Complexion was ashen, extremities cold and wet, pupils slightly dilated, hearing impaired. Treatment at first was $\frac{1}{30}$ gr. strychnine with $\frac{1}{100}$ gr. nitroglycerin, hypodermically, and during the first one and one-half hours after the bite he was given, in all, by mouth and hypodermically, in small doses frequently repeated, $\frac{1}{16}$ gr. strychnine, $\frac{1}{35}$ gr. nitroglycerin, $\frac{1}{35}$ gr. atropine, $\frac{1}{4}$ gr morphine, one ounce aromatic spirits ammonia, and six ounces of the best brandy, besides using artificial heat. Bowels, kidneys, and skin were kept active. In nine hours the pulse was nearly normal, and consciousness was restored. In four or five days he had completely recovered. The tarantula that bit him was five inches long and of a brown color.—*Fort Wayne Medical Journal-Magazine.*

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held October 13, 1902.

DR. ANDREW H. SMITH, PRESIDENT, IN THE CHAIR.

A Symptom Indicating the Probable Development of Mastoiditis, and the Necessity for Early Operation.—Dr. H. A. ALDERTON of Brooklyn read this paper. He reported case of Mrs.——, who was recovering from an attack of tonsilitis, and while blowing her nose, had felt something give away in her ear. She developed an earache, which persisted in spite of the administration of morphine. Examination showed some tenderness around the tragus and antitragus; both osseous canals congested; the dermal layer of the right membrane swollen, dull and light gray, with underlying congestion; the left membrane intensely congested and slightly bulged, with beginning bleb-formation on the surface. These symptoms becoming aggravated in the course of several hours, nitrous oxide gas was given, and both membranes were thoroughly incised in the posterior half. Immediately on incision of the left membrane, a quantity of sero-purulent secretion, possibly also sanguinolent, was forcibly propelled from within the tympanic cavity out through the perforation by gas under pressure, to the accompaniment of an explosive noise, distinctly heard at a distance of eight or ten feet. The fluid particles were driven out so as to spatter the speculum and the hand of the operator. Pain still continued, and the following day examination showed the left osseous canal intensely congested; membrane also intensely congested, and the bulging Schrapnell membrane. The mastoid was tender, especially over the antrum. The same condition existed on the right side. Under nitrous anæsthesia, an internal Wilde's incision was done on both sides. The following day operation was performed. The outer table of the mastoid process was normal. The cellular structure was greatly congested and friable. Granulation tissue under pressure filled the antrum and a large cell below, and to the outside of it. Four days later it became necessary to operate on the right mastoid, where the same foci of infection was found in the antrum and the large cell below and outside, but these cells, instead of being filled with granulation tissue, now bubbled over with pus.

The greatest interest in this case lies in the fact of the existence of gas under pressure within the tympanum and the bearing this has upon the development of mastoid inflammation. The gas was evidently the product of bacterial development, possibly from an otherwise inocuous bacteria, such, for instance, as the Aerogenes capsalutus; or it may have been produced by an extraordinarily virulent bacterium. If the gas is the product of an inoffensive bacteria, existing in a mixed infection, then we see how it acts mechanically to disseminate infection early and far. The Eustachian tube being closed, the only escape the gas has is in the mastoid antrum and cells carrying along with it the exudate thrown out within the tympanum; this gas and the exudate contain the more pathogenic bacteria. The presence of gas within the tympanum at the time of a primary incision of the tympanic membrane for an acute middle ear abscess seemed to him to be an indicating symptom of the probable development of mastoid empyema, and the necessity for early operation on the mastoid process.

Dr. GORHAM BACON said that the presence of gas as a symptom of mastoiditis was infrequent. He had occasionally seen it manifested after incising the drum membrane, but he had never had a case that was followed by mastoiditis. With regard to the time to operate in mastoiditis, it was a puzzling question to decide, and he relied more upon the bacteriological findings than anything else; when streptococci were present, operate.

Dr. EDWARD B. DENCH said that the presence of gas in the tympanic cavity was brought out first by Dr. Blake and himself years ago, and it was then stated that the development of gas was the result of acute inflammation of the middle-ear and was an indication of its virulence. When present, and he had seen the condition three or four times, he always suspected mastoid trouble. When the pain was severe enough to demand an opiate, he believed in incising. When a streptococcic infection was present, he advised operating early and thoroughly. If a streptococcic infection on one side and a staphylococcic infection on the other, he operated upon the streptococcic side. He thought the keynote to the paper was early operation in doubtful cases; in such cases the early operation will better the hearing.

Dr. FRED WHITING related four cases presenting somewhat the same features as the one reported by Dr. Alderton; in three, there was a pneumococcic infection; in the other, streptococcic. In the former one may escape operation, but in the latter, operation must be performed.

Infection with the Bacillus of Dysentery, with Special Reference to Its Rôle in the Summer Diarrhœas of Children.—DR. SIMON FLEXNER of Philadelphia considered the character of the diseases, which are now associated with the occurrence of the bacillus dysenteriæ, with the view to explaining the wide divergence in symptoms and lesions. He asked that the disease be characterized, not by its symptomatology, or pathological anatomy, but by its etiology, and in speaking of dysentery he wished to be understood as referring to that disease, or group of clinical manifestations, caused by the bacillus of dysentery, which was described in 1898 by a Japanese. The modern tendency is to utilize more and more the etiology in the differentiation of diseases. The study of the causation of dysentery has tended more and more to bring out, within the last three or four years, the fact of a specific organism occurring in this disease. Admitting such an organism as the cause of the severer forms of dysentery, if it is found associated with the lighter forms of the infection, it must equally be considered a cause of that class of cases. How can we prove that such an organism exists? It is not a habitat in the intestines and it is never found in a state of health in the intestines. They can be proven, not only to be pathogenic organisms, but also, when introduced into human beings in the state of pure cultures, they will give rise to symptoms of dysentery, and the blood changes have appeared identical with those that occur in accidental infection. He believed that within the next three or four years the proof of the existence of this organism will be more convincing than that of any other, such as that of typhoid fever. It is an organism that has not only found been in one or two localities, but, since 1898, wherever it has been looked for, when proper methods have been used, it has been found in cases of dysentery.

Dysentery is a disease that is endemic in Japan, and during the spring and summer there are thousands of cases; it disappears from that locality during the winter, although sporadic cases appear now and then. The mortality is about 40 or 50 per cent. The organism was isolated in a small number of cases by Shiga in Tokio, and since it has been found in the East, in the Philippine Islands—where acute dysentery is endemic—and sporadic cases have appeared in the United States. In 1899 it was found in Germany and, in other places, it has been found in the wake of troops which returned from China after the late disturbances.

What is the type of dysentery as determined by the lesions in the intestines with which the organism is associated? In this country we have a specific type, which is to be differentiated from the heterogeneous mass of things called dysentery, and called amœbic dysentery; therefore, it would be proper to speak of the form of disease in reference to our knowledge of the latter form. This form is characterized by amœba in the intestines, and is known as a chronic disease. There is little or no information as to the early onset of it: cases of amœbic dysentery are not examples of an acute dysentery. The lesions in the intestines in amœbic dysentery are quite definite, localized in the large intestines; and are destructive, as a rule, especially in the submucosa, and are unattended with any pseudo-membrane; there is also thickening of the gut. In these cases, the particular organism, bacillus dysenteriæ, has not been discovered. Within the last year or two two cases of amœbic dysentery of acute character have been reported from the Philippine Islands. The particular form of the disease that is associated with the bacillus dysenteriæ is the acute form.

What is the type of the lesion associated with the organism? It is that type which occurs in the lesion commonly thought of in pseudo-membranous dysentery, or colitis. Sometimes the membrane is extensive; sometimes it is absent The question of the membrane or ulceration has nothing to do with the stage of the disease; every case of dysentery goes on to the production of chronic lesions and symptoms. Without reference to their mode of occurrence, whether endemic or not, there can be recognized two types of the disease, viz., the acute dysentery, and the chronic form, the latter with symptoms extending over a long period of time with probable exacerbations due to fresh developments of the disease; in this latter class we should look for and find the organism.

If the disease is caused by a single organism, we can the better understand how it is possible for this microorganism to be associated with other diseases apparently so different in character as those which occur in some of the diarrhœas of infants. Last summer, in connection with the Rockefeller Institute for medical research, the speaker was given an opportunity of studying the causation of summer diarrhœas in infants. The work was carried out near Baltimore, in the Thomas Wilson Sanitarium, which is only open during the summer, and deals only with cases of acute illness in young children. The work was carried on by two medical students who were specially fitted for this work The technique, which took Dr. Flexner four years to perfect, has already been published. They worked upon fifty cases of the disease, which was characterized by an acute onset, elevation of temperature, disturbances of digestion, presence of mucus and blood at some stage of the disease in the fæces, etc. Among these fifty cases they never failed to find the organism.

What will be the value of the discovery of a specific organism in dysentery and in certain forms of intestinal infection in children? The greatest value, of course, comes to us in the assistance it gives in the prevention of these infections and in the cure of them. With regard to the prevention we should first try to discover where the organism is to be found in nature; about this nothing has been learned, although it has been looked for repeatedly. Although it may be assumed that it may be present under normal conditions in the intestines, yet it has never been found. Where they exist in external nature he did not know. Contaminated water as a carrier of disease is well known; under certain conditions, it is an organism that gains access to water, like the cholera bacillus, and, like the cholera bacillus, it is readily destroyed by hot water. Therefore, whenever water comes under suspicion it should be boiled and the organism destroyed.

It has been found possible to protect small animals from the infection by this organism, which is a pathogenic one. Following out the ideas of vaccination, he found that the guinea-pig could be successfully vaccinated by the attenuated virus against the living organism. He asked what could be the value of this vaccination procedure; would it be justifiable to vaccinate troops? If the American troops were to be sent into the interior in the Philippine Islands, where boiling water is out of the question, such vaccination might possibly be of service. Of how much benefit such a procedure will be can only be determined by time. What he now hoped for was the production of a serum which might be of value therapeutically. First, we must establish the fact that the organism is the cause of this class of affections occurring in children. In doubtful cases the blood may be tested for the agglutination reaction. From the evidence gathered last summer, it was found that more than 80 per cent. of the cases can be agglutinated when the organism was found in the dejecta. It was also determined that the reaction occurred earlier than in typhoid fever, in a fair per cent of the cases it occurred as early as the third day; in 50 per cent. of the cases it occurred after the sixth; it always appeared before the tenth day. Of course, it is far better to have access to a laboratory, and so not wait for such reaction. Within twenty-four or thirty-six hours its presence can be established with certainty. If a serum can be produced that is harmless, it might be justifiable to use it without waiting for the test. He believed that it was important now not to assume from the clinical symptoms alone that every case was an infectious case, and that we should examine the dejecta several times.

Regarding the success that has attended the use of the serum, he said that he had prepared a serum that would protect guinea-pigs, but the short time would not permit him to express himself with regard to its real value.

Dr. **Francis Delafield** said that it was a difficult matter to cover the subject of inflammations of the colon, and that different countries presented different characters of the inflammation, and that one experience in one country would be different from that in another. He believed that these gaps in our knowledge were likely to be filled by such work as that in which Dr. Flexner was engaged. With regard to the practical purposes of prognosis, he feared that we were not yet beyond the stage of local experiences. Local experiences count for a great deal. Here, in New York, whether one calls it dysentery or not, certain cases are seen of a certain type which are seen quite regularly. You see an acute inflammation of the colon, which is attended with congestion and increased production of mucus, and which attacks adults and children; the inflammation may be found in the rectum only, or it may affect the whole colon; if only the rectum is affected, whether adults or children, the inflammation regularly runs its course inside of a week, and the patients regularly get well; if, on the other hand, the whole length of the colon is affected, the adults get well, but the children die.

Again, as a matter of experience, especially in hot weather, the adults more than children are attacked with acute inflammation of the colon, which is attended with the transudation of serum; they do not pass fecal matter, but fluid which is serum that has been transuded into the intestine; this sometimes amounts to one quart at a dejecta. In adults this is not fatal; in children it may possibly be fatal. Again, one finds a form of inflammation of the colon which is not at all common, in which there is an infiltration of the connective-tissue coat of the colon with pus, similar to that which occurs in the stomach under the name of phlegmonous gastritis. This form occurs in both adults and children, and, so far as the speaker knew, was always fatal. It behaves in the same way as a streptococcic inflammation. Again, there may be met with inflammations of the colon with necrosis or death of the glandular structures, or of the connective-tissue coat, or both, or of the whole walls of the colon. In adults the iaflammation may involve the glandular coat, only forming small ulcerations, with a small amount of productive inflammation. Acute cases run about three weeks; chronic cases may last for months Regarding the bacteriology of these, he knew nothing There were two groups of cases of colitis which, he believed came under Dr. Flexner's category of dysentery which occurred in the tropics and temperate zones, and the variety seems to depend upon the extent of the colon inflammation and the intensity of the infection. He believed that these should be classed as dysentery. It seemed to him that amœbic dysentery was not so very rare and he was surprised at

Dr. Flexner's statement to the contrary. He had seen cases in New York, and enough of them to classify them into cases of severe, acute, amœbic dysentery, and mild, acute, amœbic dysentery, or colitis. The mild cases get well, but the severe cases usually die. In the severe cases the whole length of the intestine appears to be involved in the inflammatory process.

Dr. L. Emmett Holt said that the clinical picture was a typical one, and frequently seen about New York, and these cases he believed to be due to this organism. He thought we were on the eve of great progress in this direction.

Dr. Edward K. Dunham had seen four cases in Maine last summer, two occurring in adults and two in children, and in these cases the bacillus was found. In all of them the agglutination reaction was distinct.

Dr. Henry Dwight Chapin thought that the cause might exist in milk, and this might be a fruitful field for future study. He was impressed with what Dr. Delafield had stated with regard to locality; he had found the death rate from this disease in different localities to be quite inconsistent; for instance, in certain years the death rate in the country would be enormous, while in the city it would be low; in other years the reverse would hold. It did not appear to him that such could come from the milk, because children in the city drank of milk from the same source as those in the country. Some local condition must prevail to produce such differences.

Dr. James Ewing referred to certain cases that occurred among the troops at Montauk Point in 1898, in the general hospital. Some of these came to autopsy, and showed slight lesions but an abundance of amœbæ in the discharges.

Dr. Henry Koplik said that there were certain cases occurring in children and infants in which the Shiga bacillus was found, and which were cases of true dysentery. It was interesting that, a few years ago, the profession wished to exclude the term dysentery in children's disorders. The Shiga bacillus found in children corresponded exactly with the bacillus found in adults. The term "summer diarrhœa" was a collective one; certain cases were due to the streptococci. All cases of summer diarrhœa certainly were not due to the Shiga bacillus, although occasionally the Shiga bacillus was found in the diarrhœa of children and infants.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON OTOLOGY.

Held on Thursday, October 9, 1902.

James F. McKernon, M.D., Chairman.

A Case of Delayed Healing of Extensive Mastoid Wound Treated by Means of Skin Graft.—Presented for Dr. Wendell C. Phillips by Dr. Thomas J. Harris. The patient was a young man who first came under Dr. Phillips' observation in February, 1901, complaining of mastoid symptoms which had set in on the previous day (Wednesday). A complete internal paracentesis was immediately done, but this failed to give relief. An ice-coil was applied until the following Monday, when a mastoid operation was performed. This revealed extensive disease of the bone. Since the primary operation in February, 1901, three additional operations had been performed upon this patient by Dr. Phillips, the last one in April of the present year. All of these were undertaken for the removal of small pieces of diseased bone. These repeated operations left such an extensive wound that it was determined to make an attempt to close it by means of skin grafts. Two such attempts had been made, the last one ten days before, and had proved very successful. This expedient of skin grafting, Dr. Phillips thought, might be utilized advantageously in the delayed healing of many cases of extensive mastoid wounds.

Dr. Edward B. Dench thought the method advocated by Dr. Phillips, and illustrated in this case, was a very valuable adjunct to our means of healing these old mastoid wounds. The speaker said that the same idea had occurred to him, although he had never practised it. Another method that had suggested itself to him was to fill the cavity of the wound with blood, and then, after the clot has begun to organize, to cover it with skin grafts.

Dr. William P. Brandegee said that in order to correct the pitting that often occurs in the mastoid wound, he irritates the tissue with a dull curette, sufficiently to produce free bleeding, and then pack the cavity lightly with gauze covered with balsam of Peru. This procedure can be repeated if necessary.

A Case of Malignant Growth of the Middle Ear Involving the Cranial Cavity.—Presented by Dr. Edward B. Dench. The patient was a child, eighteen months old, who was brought to the clinic three weeks ago. The only history obtainable was that there had been a slight watery discharge from the ear for about ten days; that during this time the child had been restless, and, coincident with the ear trouble, the mother noticed that the child had become cross-eyed. The latter condition was found to be due to paralysis of the right external rectus muscle.

Upon examining the ear, the canal was found to be occupied by a tumor which was apparently covered with a thin layer of epithelium. The forcible use of the probe caused this tumor to bleed. A small section of the growth was removed and sent to the pathologist, who reported that it was composed of granulomatous tissue, the surface being covered with epithelium.

The child was operated on by Dr. Dench two days after admission. The typical mastoid operation was done, revealing a cauliflower-like growth occupying the region of the cortex, lying over the antrum and tympanic bone, involving the cranial cavity and extending nearly to the apex of the petrous pyramid. The mass was removed as thoroughly as possible with the curette, together with the softened bone that surrounded it. The entire specimen was submitted to Dr. Dixon, and he reported that it was an endothelial sarcoma.

Since the operation the child has been doing fairly well, but there are evidences of are currence in the deeper portion of the wound. The question arises whether any further surgical interference is justifiable, in view of the probability that no matter what is done it can only bring a temporary improvement, as these growths are very malignant and tend to reproduce themselves with the greatest rapidity. Dr. Dench said that, in view of the child's good general condition, he felt inclined to make another attempt to thoroughly extirpate the growth and, at the same time, ligate the carotids in order to prevent, or at least, retard, recurrence by cutting off the blood supply of the parts.

A Case of Epithelioma of the Tragus—Presented by Dr. Horn. The patient was a married woman, forty-eight years old, whose previous history was apparently negative. About four years ago she first noticed a small ulcerated lesion on the auricle of the right ear. It disappeared for a time, but reappeared, and during the past four months it has developed into a typical epithelioma, with superficial, exuberant granulations. These are now beginning to disappear. There are no glandular enlargements. No microscopical examination has been made.

Dr. Dench thought the lesions looked very much like lupus. Some time ago, the speaker said, he reported three malignant growth, of the auricle. In one of them, all the glands on the corresponding side of the neck were involved and had to be extirpated. This patient was alive and well four years after the operation. In another case, one of melanosarcoma involving the auricle, the operation was followed by a slight recurrence; the patient was again operated on, with complete relief. The results in these cases are usually exceedingly good, if they are handled promptly.

A Case of Persistent Mastoid Pain After Operation.—Presented by Dr. THOMAS J. HARRIS. The patient was a woman, twenty-four years old, who came under the speaker's observation last April. She complained of pain over the region of the right mastoid, and there was some elevation of temperature. She gave a history of an old suppurative trouble of the ear, but there had been no purulent discharge for several years. Inspection of the ear showed that the drum membrane was entirely gone. After keeping the patient under observation for two weeks, a very complete mastoid operation was done. No pus was found, and there was very little diseased bone. The wound healed without any trouble, and the patient was discharged at the end of three weeks. Shortly after the operation she began to complain of pain at or near the site of the mastoid incision, and this has persisted, more or less continuously, ever since. At times, it is quite severe. Occasionally, she also suffers pain over the opposite mastoid, upon which no operation was done. The patient is well nourished, and holds a position as a clerk.

Dr. J. O. TANSLEY referred to a similar case which proved to be of hysterical origin.

Report of Cases and Technique of Procedure in Establishing Hearing for Deaf Mutes.—Dr. MAURY M. STAPLER of Macon, Ga., presented a report of eighteen cases of deaf-mutism, twelve congenital, and the rest of long standing, which had been treated by the author by means of an apparatus of his own invention to which he had given the name "Rarefier." It consisted, essentially, of an aspirating pump, to which a short piece of rubber tubing was attached; this tube divided into four branches, two of which were inserted into the patient's nostrils, and two into the ears; then, by means of the air-pump, the air in the middle ear could be rarefied to any desired degree and the drum membranes relaxed, or the middle ear could be inflated and the membranes rendered tense. In some of his cases, Dr. Stapler said, the result of this treatment was almost marvellous, even in cases of congenital deaf-mutism. In others the effect was less striking, but very satisfactory. Dr. Stapler was given an opportunity to try the apparatus upon a girl of twelve years who had been deaf since infancy, as the result of an attack of cerebrospinal meningitis. It produced absolutely no effect upon the hearing in this case.

Symptoms and Course of Acute Catarrhal Prostatitis.—The onset of this form of disease is always rapid, it often developing over night; the patient appearing one day with symptoms of bulbomembranous urethritis only, and the next morning giving all the evidence of prostatic involvement. The symptoms are almost entirely objective. The patient complains of frequent and painful urination, pain referred to the perineum. Examination of the prostate per rectum is negative; examination of the urine by the three-glass test shows the first portion very cloudy, the second somewhat clearer, and the third again cloudy, and containing gonococci, comma-shaped organisms from the prostate, prostatic fluid, and often a little blood. This terminal hæmaturia and the comma-shaped organisms, accompanied by prostatic tenesmus and frequency of urination, is almost pathognomonic of the disease. The inflammatory process is confined to the prostatic urethral membrane and the mouths of the follicles; there is congestion and reddening of the epithelium of the prostatic urethra and swelling of the mouths of the follicles. The discharge is found to contain desquamated epithelial cells, gonococci, pus-cells, and prostatic fluid. The process runs an acute course, and may end in resolution or in the follicular or parenchymatous forms.—Dr. JAMES W. WILTSE in *Albany Medical Annals*.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 25, 1902:

	Cases.	Deaths.
Measles	53	3
Diphtheria and croup	285	32
Scarlet fever	118	8
Smallpox	3	.
Varicella	21	..
Tuberculosis	212	143
Typhoid fever	154	24
Cerebrospinal meningitis	..	..

Malarial Fever in the Malay Peninsula.—In a recent medical report to the Prudential Insurance Company, Dr. E. O. A. Travers of the State of Selangor Federated Malay States, S. E. Asia, writes as follows: "In connection with the prevalence of malaria on the coast, and in other parts of the State of Selangor, it has been noticed that certain pools and stagnant drains, which are at one time swarming with the larvæ of the anopheles mosquito, are found at other times to be absolutely free from them. The appearance of large numbers of anopheles is almost invariably connected with a marked increase in the number of cases of malarial fever. It has been noted that the larvæ of the culex varieties do not appear and disappear in this way, but are always to be found in almost any pool of stagnant water. During the present year careful observations will be made with regard to the habits of the anopheles and their connection with the increase or decrease in malarial fever. Reference to the above figures will show that malarial fever has become a very serious cause of sickness and mortality in this State. During the past year 5,445 cases of severe illness causing admission to hospital and 322 deaths were due to this disease, as against 2,065 admissions on account of beri-beri with 311 deaths. The Klang district has suffered very heavily during the year, investigations made by District Surgeon Dr. Watson proved the presence of large numbers of anopheles mosquito in innumerable pools and drains in the town, which is low and flat and has a large swamp right in the middle of it. I am glad to say that provision has been made for extensive drainage works to be made during the present year, with a view to improving the health of the town. A severe outbreak of malaria, causing many deaths, occurred at Port Swettenham during the latter half of the year, energetic measures in the way of filling, draining, and felling jungle were carried out, and have been rewarded with, at any rate, considerable temporary success. Since July 1 all cases of malaria fever admitted to those hospitals in charge of district surgeons have been diagnosed by the microscope. The above figures, however, show clearly that all varieties of malarial fever are met with in Selangor, also that, as in other parts of the world, the malignant type is the more common and the most fatal, whereas the quartan type is the rarest and the least dangerous.

"In the treatment of malaria, fair trial was given to the various methods of administration of quinine. It was found, with very few exceptions, that a satisfactory cure could be effected by giving quinine by the mouth in solution, complete rest during dosage by quinine being essential. Subcutaneous injection was found to cause local inflammation, and often lead to the formation of a slough —this form of injection of quinine has therefore been entirely given up. Intramuscular injection has been largely carried out and has been found to be extremely useful in cases which resist the action of quinine by the mouth, or which are admitted to hospital with dangerous symptoms. Provided that ordinary care is taken to see that the syringe is clean no sloughing or abscess formation has been found to follow intramuscular injection. The only objection to this method of administration is the acute pain caused during the operation. Intravenous injection has not been very largely practised. In many cases it is not easy to introduce the needle into the vein, and keep it there, and often an injection has been partly intravenous and partly subcutaneous, with all the subsequent drawbacks to the latter method. All patients suffering from malarial fever are now carefully protected by mosquito curtains, a certain number of beds being set apart for malarial cases in each hospital. The free use of kerosine oil in anopheles infested pools has been largely carried out in infected districts, with apparently a good deal of success. Sanitary measures, among which may be included draining and filling in of pools, and felling of jungle in the neighborhood of houses, have been actively carried out during the year in many parts of the State."

Dearth of Surgeons in the United States Army.—The following article, which appeared in the *New York Tribune* on October 12, puts the situation, as regards the cause of the scarcity of candidates for the medical service of the United States Army, briefly and well: "When commissions in the United States Army go begging there must be causes worthy of investigation. That condition now exists in the medical department of the army, where there are forty vacancies in the grade of assistant surgeon. The board in session at Washington has examined a large number of applicants, out of which only a few have been selected. By some officers, who have discussed the matter, it has been said that the examinations are too severe, and that a young physician must rank far above the general average to be able to pass them successfully. The rank of the new assistant surgeon in the United States Army is first lieutenant, with about $1,600 a year pay, not enough to lure many men from the quiet path of general practice to the strenuous work of the army surgeon. After five years' service the assistant surgeon advances to the grade of captain, and there he remains, unless something extraordinary happens, for twelve or fifteen years, and if he is then still physically competent to perform the duties of the place, he may become a surgeon with the rank of major. The Army Register shows that a few surgeons gained the gold leaf in less than ten years, and that one lucky man reached the grade of major in about seven years after his captain's commission was issued. But the majority of the sixty majors in the department had to wait from twelve to sixteen years for the promotion. This condition is believed by many physicians to be one reason why the examining board has had mediocre material to deal with, and has been compelled to reject all but five of the candidates for the vacancies."

The Metric System in Great Britain.—The United States Consul-General at London forwards a letter from the Secretary of the Decimal Association of England on the subject of the agitation now going on for the adoption of the metric system in Great Britain, of which the substance is as follows: "There are 200 members of the House of Commons in favor of the adoption; sixty town councils have passed resolutions in favor of the movement; all the chambers of commerce, nearly all the school boards, the trade unions, and many scientific societies are likewise in favor: the Prime Minister of the colonies, lately in session in London, passed a resolution urging the adoption of the measure, and the Prime Minister of England is also very favorable. It is probable that at the next session of Parliament the necessary bill will be passed. If England enters the metric union the United States will probably follow. Then we may look out for expensive chaos in the machine shops, architectural offices, etc., throughout the country, and for a plentiful crop of law suits regarding titles to land that must arise when the dimensions of city lots are expressed in decimeters instead of in feet and inches. The metric system has been legal in the United States since 1866. Any one who wishes to use it can do so. All persons to whom it is an advantage already use the metric system. Why should it be forced down the throats of those to whom it is of no advantage?"—*New York Sun.*

Rome More Healthful.—The marked change of opinion as to the sanitary condition of Rome in summer is exemplified by statistics just issued, showing that in July, August, and September of the present year 9,734 foreigners visited Rome, Americans heading the list with 3,020, closely followed by Germans, who numbered 2,875. Formerly Rome was deserted during these months and the hotels were closed, because of the belief that the heat was unbearable and that malignant malaria was prevalent.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending October 25, 1902:

		CASES	DEATHS
SMALLPOX—UNITED STATES.

THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEY ACCOMPANIED BY PYURIA.*

By RAMON GUITÉRAS, M.D.,
NEW YORK.

I AM aware that in presenting the subject in this form I am transgressing the traditional classifications, and yet I am satisfied, from my experience in consultation with practitioners, that I am presenting the theme from the viewpoint from which many of them regard it in actual practice.

When we look over the textbooks of renal surgery we are impressed with the fact that writers still classify, under "suppurative diseases of the kidney," a certain group of conditions, and completely ignore certain others that are attended by suppuration, and are, perhaps, primarily the most frequent causes of it. The reason of this is, probably, because until recent years our knowledge of kidney surgery has been limited, and the diseases of this organ were considered more from a causative than a pathological basis. At present the diseases of the kidney spoken of as "suppurative" are the so-called suppurative nephritis, which consists of a suppuration of the organ, due to an infection through the blood, or to complicating traumatism, or from extension from contiguous organs, etc.; and the so-called surgical kidney, an extension of the inflammation upward from the bladder.

The other conditions referred to, giving rise to suppurative disease of the kidney, and, consequently, to pyuria, are renal calculus, tuberculosis, and tumor. These are almost always accompanied by infection and by suppurative complications in their later stages, and are not usually considered real suppurative diseases of the kidney, because they are classified as independent troubles with secondary suppuration.

The practitioner of the present time, however, if he finds a patient with pain in the region of the kidney, or, perhaps, with a colic descending along the ureters or transmitted in various directions, associated with frequency of urination and a moderate amount of pus, and, perhaps, blood in the urine, immediately thinks of renal calculus or tuberculosis; or, perhaps, of tumor if the amount of blood in the urine has been sufficient to constitute a marked hæmaturia, especially if there has been no history of urethritis, cystitis, or prostatic hypertrophy. If, on the other hand, there has been a history of urethritis or vesical disease, he will think of an ascending pyelitis or pyelonephritis. In all such cases, therefore, it remains for the surgeon to determine definitely the variety of the disease and, then, the best method of treating it.

To study our subject more carefully, then, we must consider it from a pathological basis, and having concluded what, in our opinion, the surgical diseases of the kidney are that are accompanied by pyuria, we can show the methods of fitting certain clinical groups of symptoms to a certain set of renal lesions.

I. Classification and Definitions.—Probably the simplest pathological classification of the renal diseases accompanied by pyuria is: pyelitis, pyonephrosis, suppurative nephritis, and pyelonephritis.

1. *Pyelitis.*—An inflammation of the pelvis of the kidney, due, usually, to the extension of an infection from the lower parts of the urinary tract, generally from the bladder (cystitis), or to the presence of stone, followed by secondary infection, etc

2. *Pyonephrosis.*—A pyelitis, which is accompanied by obstruction in the pelvis or ureter, giving rise to a dilatation of the pelvis and calyces, which may be temporary or permanent, and which gradually dilates and destroys the kidney itself. The contents of the sac consists of urine and pus Such a condition may be due to infection in the pelvis of a movable kidney, obstructed by ureteral kinking, stricture, or by pressure upon the ureter by adhesions, or to tumors or stone in the ureter or renal pelvis.

3. *Suppurative Nephritis.*—A suppurative condition of the kidney proper, not associated with any involvement of the pelvis, as in cases of hæmatogenous infection of the kidney, traumatism with infection, a renal abscess due to pyæmia, or to stone or to tubercle in the renal tissue proper, complicated by pyogenic infection.

4. *Pyelonephritis.*—A condition which can best be described as a combination of suppurative pyelitis and nephritis. Here the suppurative process may be first found in the renal pelvis, and then involve the kidney substance; or it may be first in the kidney and affect the pelvis of the organ secondarily, the avenues of communication in either case being the straight collecting tubules and their mouths in the papillæ. In ascending pyelitis, when due to calculus or tuberculosis, a suppurative pyelonephritis is usually present at some time or another in the disease, if advanced far enough. Suppurative nephritis may, however, exist without involving the renal pelvis as seen under (3).

To summarize from an etiological standpoint, it may be said that the three varieties of kidney disease that most often are the causes of pyuria are, in the order of their frequency: (1) A suppurative pyelitis or pyelonephritis, due to an ascending infection; (2) A suppurative pyelitis, pyonephrosis, pyelonephritis, or renal abscess secondary to stone in the kidney; and (3) A suppurative nephritis, pyelitis, or pyelonephritis, secondary to tuberculosis of the kidney.

II. The Clinical Problems of Pyuric Cases.—Having thus defined briefly the varieties of suppurative inflammation met with in the kidneys, pathologically and etiologically, we may pass on immediately to the consideration of the problems which present themselves to us in this group of clinical conditions whenever a patient with pyuria is brought to us for consultation. These problems may be resumed in one sentence, namely: *Given certain local symptoms of renal disease, and the pres-*

ence of pus in the urine, coming from the kidney, what is the condition of the patient?

(*a*) *The History of the Case.*—As in all clinical problems, the history of the case plays an important rôle in directing our investigations in a case of pyuria. The special points to be noted in the family history of such a case are the presence of cancer, tuberculosis, stone, gout, or rheumatism.

In the previous history the chief points to be considered are the occurrence of urethral infection, cystitis etc.; the presence of renal colics, lumbar pain, chills, fever, digestive disturbances, headaches, emaciation, frequency of or painful urination; and voiding thick, cloudy, or bloody urine, or of highly colored urine with a deposit of gravel.

The symptoms of suppurative conditions of the kidney, which are present when the practitioner first sees such a case, vary greatly in severity, and may be vague and faintly marked, even with an advanced lesion in the kidney. As a rule, however, although some of the same symptoms accompany all these varieties of disease enumerated, there are always one or more of them in the history of the case, that make it especially distinctive. The most important symptoms of suppuration are (1) The local effects of the process pain, tenderness, and, perhaps, lumbar tumor; (2) Pus in the urine, and (3) The general effects of the process (sepsis, uræmia).

In *pyelitis* there may be nothing but simply frequent urination, and a vague sense of discomfort, or a constant pain in the loin, in the way of symptoms complained of. At other times, especially if a pelvic stone be present, the pain in acute cases is severe and intermittent, showing itself in attacks of true renal colic. Fever, chills, and sweating are, at times, prominent features in such a case, but are often mistaken for other conditions. The urine may be diminished in quantity from the reflex affection of the opposite kidney, or may be increased and of lower specific gravity as a result of a mild irritation produced so near the parenchyma. The lumbar pain is reflected, as a rule, downward, in exceptional cases, backward and upward, and may be increased on motion of thigh; abdomen and diaphragm in exercise, coughing, etc. In chronic cases of pyelitis there is usually less pain, and all the symptoms of the acute form are simply milder. Fever, if present, may be intermittent, and may resemble malaria. Occasionally the case may exacerbate into the acute form, and then the pain becomes more intense, the urine diminished, or anuria supervenes if there is obstruction. Acute constitutional symptoms accompanying this trouble should always remind one of impending pyonephrosis, or pyelonephritis, and the more I see of cases of so-called pyelitis with these symptoms, the more am I becoming convinced that one of the former conditions is usually present.

Pyonephrosis is also characterized by all the symptoms mentioned above, but, in addition, there is intermittent and varying pyuria, and, at times, intermittent swelling in the loin, as determined by palpation or inspection, depending upon the fact that the obstruction becomes at times complete. I have, however, seen most typical cases of pyonephrosis in thick-walled subjects, where the loin elicited no pain on pressure, and showed no enlargement.

Pyelonephritis, if acute, begins with a sudden onset, with high fever, chills, and pain in the region of the kidney. The fever may be continuous and terminate in the typhoid state, coma, and death, or else it may gradually subside, and the condition merge into a chronic one. Vomiting and other symptoms of indigestion, including hiccough, due to the uræmic condition, often occur in these cases, and are apt to mislead the diagnostician. The acute cases are often fatal, but many become chronic, and a few are relieved spontaneously by free drainage through the ureter, after rupture of an abscess into the renal pelvis.

In chronic pyelonephritis the patient exhibits, in the first place, a series of intestinal and dyspeptic symptoms, such as vomiting, diarrhœa, constipation, etc. Gradually he loses flesh and strength, and has a mild febrile movement of the septic type. There is lumbar pain, fever, chills, uræmic symptoms, prostration, coma, and the typhoid state toward the end.

It may be said that in cases in which tumor, stone, or tuberculosis are present hæmaturia is a more marked symptom. Besides this, in stone, so-called gravel is usually found in the urine; in tuberculosis there may be the signs of tuberculosis elsewhere, as in the prostate, epididymis, glands, lungs, joints, etc., and tubercle bacilli may be found in the urine; in malignant tumors the cachexia and loss of flesh will be found pronounced and progressive in the advanced stages, and metastases may be found elsewhere in the body. In cases of movable kidney the patient will probably be a woman, the affection will be found most often on the right side, and the symptoms of pain, nervousness, and digestive disturbances will have preceded those of suppuration.

A patient suffering from these conditions is usually seen with his physician, but in case he is a walking patient and calls at the office alone, he generally brings a letter from him giving the past and present history with a report of the urinary analysis. This will, of course, tell if the patient has pyuria, and we will have this important point to start out with.

The information obtained in this way is very valuable, but it should not deter us from making our usual systematic examination, for it is impossible to know how much reliance we can place on the opinion and observation of others, as even a most experienced practitioner who has not made a special study of kidney diseases may have arrived at the most erroneous conclusions.

(*b*) *The Physical Examination.*—The outline of the examination of a walking patient coming to the office is as follows: Inspection, palpation, percussion, rectal, and urethral examinations. While this examination is being made, a sample of urine taken in the office should be examined by an assistant, to determine as well as possible, by a hasty analysis, the presence of blood, pus, epithelium, etc. The urinary report and the local examination, together with the past and present history, will give us a fair idea of what the patient is suffering from; after which it will only be necessary to take certain other steps to prove that we are right in our provisional diagnosis.

Before taking the patient into the examining room, his temperature and pulse should be taken. The temperature shows whether or not an acute process is going on in the organ. It is often remarkable to find a patient with a temperature of 102° to 103° F. with kidney involvement, who comes into the office simply complaining of an attack of indigestion. The pulse is also important, as it not only tells us whether a febrile process is going on, but also shows whether arterial changes are taking place—an important factor to note in cases of kidney disease. A rapid pulse and a very slight continuous febrile movement, with an occasional exacerbation, is always a bad symptom in this class of conditions.

General inspection shows the presence or absence of œdema of the feet, or puffiness under the eyes, indicating whether or not the circulation is being interfered with, and whether or not the parenchyma of the kidney is probably involved. A cachexic look points to the possibility of Bright's disease or, perhaps, to the presence of malignant tumor or tuberculosis. A septic look shows that the patient is absorbing pus, and that the febrile movement, the presence of which has been already ascertained, is not a temporary one, but one of some duration. *Local inspection* shows us occasionally a bulging of the loin in cases of renal tumor or pyonephrosis in thin subjects.

Palpation is the most valuable means that we have of directly examining the kidney, and gives the most information as to its size, shape, position, tenderness, adherence to surrounding organs, etc. It should be performed by the bimanual method: The patient lies on his back, the thighs slightly flexed, the surgeon standing upon the side to be examined. The patient is directed to take a deep inspiration, and during the moment of abdominal relaxation coincident with expiration, the upper hand pushes firmly toward the posterior abdominal wall, so as to meet the lower hand as closely as possible. The affected kidney will usually be tender on pressure, while if a tumor, abscess or renal retention (pyonephrosis) be present, the mass will be felt between the surgeon's hands. In cases of movable kidney it is necessary to palpate the organ both in the erect and reclining positions, in order to determine its size and mobility. It must be borne in mind that the normal kidney can not be outlined by palpation, even in thin subjects.

Percussion does not show the outlines of a normal kidney, but when the kidney is markedly enlarged by a new growth, or distended by an exudate, or pushed forward toward the anterior abdominal wall, percussion may give information of value. It is generally said that tympanitic resonance over an abdominal tumor shows it to be of renal origin, as the intestine is placed over the enlargement. Naunyn and Minkowsky suggested some time ago that the colon be distended by the injection of gas, in order to bring out the retroperitoneal relations of the tumor more clearly; but this is not a useful procedure.

Phonendoscopy was suggested by Bianchi, the originator of the phonendoscope, as a means of outlining the upper pole of the kidney by percussion, accompanied by auscultation, with this instrument. I have had no experience with this method of auscultatory percussion, as it rather belongs to the internal medicine men; but Albarran, after a series of experiments at the Necker Hospital in Paris, seems to think that it is by no means to be despised as an addition to our resources in renal diagnosis.

A *rectal examination* is then made in men; a *vaginal* in women. Rectal examination shows us, in men, whether the prostate or seminal vesicles are involved, and, if made bimanually, may also tell us often whether a stone or tumor is present in the bladder. A prostatic enlargement, due to senile hypertrophy, would indicate the probable presence of residual urine, pointing to an infected bladder with, perhaps, a pyelitis or a pyelonephritis of the ascending type.

An enlarged prostate, accompanied by a febrile movement, in a young man with a history of urethritis would point to a prostatitis, or a prostatic abscess with, perhaps, a cystitis; and if associated with reflex lumbar pains would resemble the symptoms of suppurative renal disease, and it would require additional methods of examination to determine whether the symptoms were due to prostatic or renal trouble. Seminal vesiculitis sometimes give rise to pain reflected upward toward the loin, and the sacroiliac region, which might be mistaken for renal pain.

A urethral examination will tell us whether strictures are present, or whether there is an impediment in the prostatic urethra, either of which conditions might give rise to cystitis and to an extension of the inflammation upward in the urinary tract. At the same time the patient may be catheterized to see whether residual urine is present.

Cystoscopy is not usually performed at the first visit, and the examination finished, the attention is turned to the *urine* to see what additional light can be thrown upon the case from the *rapid urinary analysis* that has been made in the meanwhile by the assistant.

(*c*) *The Urinary Analysis*.—(1) *Rough Clinical Tests*.—Most practitioners have no laboratory connected with their offices, and no assistant who can make an analysis while the patient is being examined, in which case it is necessary for them to analyze the urine themselves after or before the physical examination, or to be governed by certain rapid and less accurate observations made in the office at the time of examination.

It is evident that the pus in pyuria may come from any part of the urinary tract from the external urinary meatus to the cortical portion of the kidney. A few rough tests, however, will give us a fair idea of the source of the pus.

If we can express it from the meatus, the pus is evidently urethral, and probably comes from the anterior urethra. If, in the two-glass test, the first urine contains pus and shreds, and a second portion passed immediately afterward is clear, it is evident that there is a purulent discharge of urethral origin present, or a discharge from the genital tract. If the first and second urines are both cloudy it shows either that the posterior urethra is so acutely involved that some of the pus overflows into the bladder, or, what is more probable, that there is an involvement of the urinary tract above the vesical sphincter.

When the whole amount of urine passed is found to be cloudy immediately on passing, there is no doubt that some pathological condition exists, which affects the urinary tract at least as high up as the bladder, if not higher.

Mucus.—Normal urine is almost perfectly clear as it issues from the meatus, but even in normal urines a few minutes' standing will bring out a faint cloud, which very slowly settles to the bottom. This cloud, the so-called "nubecula" of the ancient uroscopists, consists of mucus perhaps mixed with a few epithelial cells from the bladder. It is much more pronounced in women, on account of the admixture of vaginal mucus, which becomes washed away from the genitals by the passage of the urine from the urethra. In catarrhal conditions of the genitourinary tract, especially in cystitis, prostatitis, and urethritis, the normal mucus cloud is markedly increased, so that the urine appears cloudy soon after being voided, and that the cloud sinks more rapidly to the bottom. A rough test for mucin, which is the proteid substance contained in the mucus cloud, consists in diluting the urine with equal parts of water and adding acetic acid, a few drops at a time, until a precipitate of mucin is formed, which is soluble in an excess of acetic acid. If the urine contains albumin, mucus may be detected by first precipitating the albumin by means of heat, and then testing with acetic acid for mucin. Other more delicate tests may be applied to detect the presence of mucin, but, as a rule, unless present in very large quantities, mucus may be distinguished from pus in the urine by naked eye inspection, the characteristics of the mucous cloud being that it floats longer and it is less opaque, less dense, and more evanescent than the pus cloud.

Phosphates may give rise to cloudiness in the urine when there is an excess of the earthy or triple salts, and when the acidity of the urine is lowered, thus lowering the solubility of the phosphatic elements. It is difficult to mistake a turbidity due to phosphates for anything else. This turbidity is generally not present in the form of a cloud, but pervades the urine uniformly, gradually settling on standing. A few drops of acetic acid added to such a urine will almost immediately clear up the urine by correcting the lowered acidity. If the turbidity were due to the presence of pus, mucus, blood, or cellular elements, it would be increased by the addition of the acid.

Bacteria, when growing in large numbers in the urine (bacteruria), give rise to a faint cloud which has a tendency to float in the middle part of the vessel, and does not settle even when the urine stands for a long time. This cloud remains practically unchanged by the addition of acetic acid.

Urates may be found precipitated in urine in which they are present in excess. Such urines are always found to be acid in reaction, and it is well to remember that a sediment occurring in acid urine can only be composed of urates, unless we have to deal with an organized sediment. Cold and certain intricate chemical conditions, which do not interest us here, increase the amount of this precipitate, while simply heating a test tube with such a urine gently over the flame will dispell the turbidity, thus showing that urates are responible for the cloudiness of the heavy dirty yellow, or brick red sediment. It is only when urates cause a general turbidity that they can be mistaken for pus. If pus were present heat would increase the turbidity instead of decreasing it.

The rare condition known as *chyluria* may be mistaken for pyuria. This condition depends upon the presence of Filaria sanguinis hominis, and is characterized by a urine which represents practically a fat emulsion in which the finely-divided oil-globules remain in suspension in the urine, producing a milky appearance. Such urine will stand for days without settling; is milky yellowish-white or pink in color, and shows a film of fat, or of cream-like flakes, upon the surface. On shaking with ether the fat is dissolved, and the urine becomes normal in appearance. Chylous urine also has the property of coagulating spontaneously on standing.

Pus in the urine shows its presence by cloudiness immediately after passing, and on standing a few minutes by a deposit of an opaque, amorphous, yellowish white sediment, which sinks to the bottom much more rapidly, than mucus. In the presence of an admixture of mucus and pus, the opacity of the sediment and the rapidity of its precipitation are lessened. In an alkaline or ammoniacal urine the pus deposit occurs as a tenacious gelatinous-looking mass which adheres to the bottom and to the sides of the vessel. On repeatedly shaking the urine it is impossible to disintegrate this mass completely, and, if it be allowed to settle and the urine decanted into another vessel, the gelatinous pus is often dislodged in a lump and precipitated in the second vessel.

The rough clinical test for pus, known as Donnes' reaction, is often of value to the practitioner, in distinguishing pus from mucus and other sources of cloudiness in the urine. This test consists in allowing the sediment to gravitate to the bottom of a conical glass; decanting (or pipetting or siphoning) the urine which floats over the sediment, and adding the ordinary solution of caustic potash, drop by drop until the gelatinous, glary, tenacious mass, which has been described above, is formed in the deposit, adhering to the bottom of the vessel and slipping out from it *en masse*. In fact, the occurrence of this gelatinous substance in alkaline urine results from the same chemical reaction that is produced in the test just mentioned. A good rule given by Tyson is that if such a gelatinous mass is found in an alkaline urine, and yet if we are, clinically, not sure that we are dealing with pus, and not merely with mucus, another specimen of urine, acid in reaction, should be obtained. If then the urine still shows a similar deposit, it may be safely assumed to be mucus. This same test may be performed also still more readily by adding equal parts of the caustic potash solution to the urine suspected, and observing the appearance of a gelatinous precipitate.

An interesting feature of some purulent urines is the occurrence of elongated plugs resembling, in general appearance, the gelatinous mass described, which sometimes are gathered in larger or smaller clumps appearing in the bottom of a tube of urine.* These plugs of gelatinized pus are the result of ammoniacal fermentation going on in the urinary passages themselves, especially in urethritis, prostatitis, and cystitis, and they are usually mixed with epithelial cells, derived from the particular portion of the tract affected.

In addition to the above rough clinical tests, which the practitioner himself can perform, *a hasty examination made by a laboratory assistant* gives us data much more complete, as it immediately tells us of the specific gravity, the presence of albumin, pus, epithelia, blood, casts, and crystals.

The specific gravity having been taken and the albumin and sugar tested for, the specimen can be centrifuged and put under the microscope, telling us almost immediately of the presence of pus. The same slide will also tell us something about the epithelia, blood, and casts that may be present. If not, there will be sufficient time for the examination of several other slides before our physical examination is over.

Pus having been noted, we know that we have to deal with *pyuria*.

Epithelia, if found in large numbers, tend to show whence the pus comes, as they are thrown off from an inflammatory area, and represent, like pus, an inflammatory product. Bladder epithelia being present in large numbers, we know that we have a cystitis. Pelvic epithelia show that a pyelitis is present, Renal epithelia indicate the presence of nephritis. Very often all these three varieties are present, showing an infection of the upper and middle urinary tract, bladder, and kidney.

Blood shows that the area is actively inflamed, that the blood vessels are enlarged by a great deal of congestion, or that erosions or ulcerations are present. It points to the possibility of tumor, stone, tuberculosis, traumatism, or inflammation due to infection. Its source, like that of pus, is indicated by the epithelia.

Casts can also be noted at a hasty examination, showing that the kidney proper is involved, and pus casts show that a suppurative process is going on. Connective tissue shreds point to a destruction of renal substance, and large numbers of crystals point to a calculus of the corresponding variety.

---

*Large thin test tubes, holding about four to six ounces and provided with a foot, are very well suited for these rough clinical and naked-eye examinations

2. *Detailed Urinary Examinations.*—We now have gained considerable information regarding our case, and can make a probable diagnosis, but to confirm it we must go still further and make a detailed examination of a twenty-four-hours urine, submiting it, if necessary, to the freezing-point test (cryoscopy). Besides the detailed urinary examination, cystoscopy, ureteral catheterization, the phloridzin test, radiography, and, perhaps, an exploratory incision should be resorted to, before we know that our diagnosis is correct as regards the lesion present and the side affected.

The examination of the specimen of a twenty-four-hours' urine should be made with great care, and if the practitioner or the laboratory assistant is not an expert, it should be given to a competent pathologist or urinologist. I use the word "competent," because in these cases the urinary examination is of the utmost importance, from a diagnostic viewpoint, as well as a guide to the decision regarding treatment. The routine examinations, as usually performed by internes or physicians who are untrained in this line of work, are *worse than useless*, as they are only misleading to the surgeon. Recently, on a number of occasions in my hospital practice, I was led to think, from the clinical history and symptoms, that the patient's condition was far worse than the urinary examination showed. I have had the specimens sent to my private laboratory for examination, and have been surprised to see that the products of pathological changes had not been noticed by the internes, and, later on, the operation showed that my laboratory findings were corroborated. I must, however, say that I believe that in all these cases my house staff examined the urine in a conscientious way, but that they lacked the trained eye and the technique so important in this line of work.

Localizing the Process—Epithelia.—We have already said that there is no way of telling whence pus cells which we find in the urine come, from a mere study of these alone, and that the clue to the localization of a suppurative process occurring in the genitourinary tract is chiefly the study of the epithelial cells that accompany them in the urinary sediment, and, secondarily, the study of casts and blood-corpuscles.

It has been asserted by numerous and excellent authorities that it is impossible to distinguish epithelial cells derived from various parts of the genitourinary tract from one another. On the other hand, studies made within recent years by urinologists have shown that each portion of the tract is endowed with epithelium, which in the urine shows characteristics that are sufficiently well marked to enable one who is thoroughly trained in the microscopic examination to distinguish the part of the tract from which they are thrown off. It is true that, even under favorable circumstances, there will always be some cells whose exact origin is somewhat doubtful, but the majority of epithelia can be located with fair accuracy, and the epithelial cells from the convoluted tubules, from the straight collecting tubules, from the pelvis, the ureter, the bladder, and the urethra, if carefully studied, can be differentiated.

Small numbers of the squamous epithelia from the bladder and from the vagina in women are to be found in normal urines, so that no significance should be attached to them. On the other hand, the presence of epithelia from other parts of the tract is a sign of some pathologic process, and the source of the epithelium is an index to the location of the lesions.

When pus cells are present in considerable numbers, and when there is, at the same time, a considerable number of epithelia from the pelvis (which are quite characteristic), we have to deal, undoubtedly, with a suppurative pyelitis—whether simple or due to stone or tubercle or tumor, we do not as yet know. If there is coincidently a large number of cells from the bladder, we have to deal with a cystitis, which may have existed before the pyelitis, and if there are many cells from the deeper layer of the bladder, and many degenerated, fatty, or granular epithelia, the cystitis is probably a chronic one.

If we find, in addition to a large number of pus cells, a considerable number of epithelial cells from the renal convoluted tubules, or from the straight-collecting tubules, we have, in all probability, a suppurative nephritis, especially if there are, at the same time, granular, epithelial, pus, or blood casts. When, in addition to all these features, there are many cells from the renal pelvis, we have to deal with a pyelonephritis.

If there is an intermittence in the pyuria, and a diminution, at times, in the amount of urine passed, we may conclude that our case of pyuria is one of pyonephrosis with intermittent obstruction of the ureter by stones, clots, etc.

We have stated above that these diagnoses are based on the recognition of a *considerable number* of pus cells and a *large number* of epithelia from one or another region of the tract. When only a *few* pus cells and a *few* epithelia are present, together with a *few blood cells*, we have probably to deal with a non-suppurative acute or subacute nephritis or pyelonephritis, or merely with a congestion or irritation of the kidney or pelvis.

Casts: Their Significance.—In connection with epithelia, casts, when found, speak for an involvement of the kidney, either in the suppurative process itself or in a secondary acute, subacute, or chronic nephritis of the non-suppurative type. The casts indicating an acute process in the kidneys are the hyaline, epithelial, and blood casts, while the granular, both coarse and fine, the fatty and the waxy casts speak for a chronic nephritis. Whenever there are pus-casts, *i. e.* casts of any type which are studded with pus-cells, or cast-like masses of mucus, covered with pus cells, renal suppuration may be diagnosticated with a considerable degree of certainty. The presence of blood casts indicates the occurrence of hemorrhages into the renal canaliculi, and may indicate only the presence of acute or subacute nephritis, but especially in cases accompanied with profuse hæmaturias and pyuria, blood casts stand for the irritation of the renal parenchyma, due to a stone, tumor, or tuberculosis, or some inflammatory condition in the kidney.

It must be remembered, however, that casts are not always present in suppurative nephritis any more than they are in the non-suppurative types. Their absence, therefore, does not exclude the presence of suppurative nephritis, provided pus and renal epithelia are present in sufficient quantities.

The size of the casts varies as to the region of the kidney involved, and this feature has been utilized very ingeniously to tell the extension of the process. Thus casts from the narrow parts of the tubules are the smallest in diameter; next come the casts derived from the convoluted tubules, and, finally, the casts from the straight-collecting tubules. When the latter class of casts with large diameters is found alone, we have a nephritis in the medullary portion only; when the convoluted tubule casts are present the cortex has been reached by the affection. Conglomerates of casts or plugs of considerable size are sometimes found in pyelitis.

Blood-corpuscles.—Next to the presence of pus, epithelia, and casts, the presence of *blood* is of significance in the diagnosis of pyuric cases. In judging urinary reports, the first rule to remember is that the presence of many blood cells, even in the urine that appears fairly normal to the naked eye, indicates the presence of an acute process or an exacerbation of a chronic process somewhere in the tract. Here, again, we stumble upon the question as to the source of the blood. Something may be told of the source of the red cells by studying these cells themselves. According to v. Jacksch, when red-blood cells are intimately mixed with the urine, so that, though present in large amounts, and deeply coloring the urine, they do not form a sediment upon standing for several hours, the hemorrhage probably took place in the renal parenchyma or in the pelvis or ureters. Red cells from the kidney are seen under the microscope as profoundly changed, devoid of most of their coloring matter, as pale yellowish rings (phantom-corpuscles). On the other hand, in congestion or hemorrhage lower down in the tract, the red cell appears, as a rule, fresher and less altered. When the blood comes from the kidneys it is usually darker and thicker than when it flows from subrenal structures. Ureteral clots may be passed, and so give clue to the source of the hemorrhage. But the chief reliance in locating a hemorrhage, or a few red cells in the urine, is to be based upon the coexistence of characteristic epithelial cells in the sediment.

Connective Tissue Element.—Connective tissue shreds found in the urine show the presence of a destructive process in the kidney, if accompanied by the presence of epithelia, pus, and blood. The extent of the destruction may be judged, to a certain extent, from the size of these shreds.

Other Tests in the Urinary Examination.—The physical and chemical examination of the urine are of great importance in these cases, and they should never be omitted, as they throw light upon the coincident nephritis of a parenchymatous or interstitial type and upon the functional value of the kidneys. Such factors as the quantity passed in twenty-four hours, the specific gravity, the amount of urea, and the total solids are important points in this regard. The refinements of diagnosis for testing the functional value of the kidneys, such as the permeability test by means of phloridzin or methylene blue injections, by determining the freezing point (cryoscopy) the amount of chlorides, etc., will now come in, if thought necessary. Such tests are as yet in the experimental stage, and, in doubtful cases, in which alone they are justified, on account of the time and trouble which they take, they are as yet not, to be fully trusted.

Having thus satisfied ourselves by microscopical examination of a urinary sediment that there is a suppurative process in the kidneys, or in the pelvis, or both, we may proceed to find by such examination if possible, the cause of this suppuration. The pus should be examined for tubercle bacilli, and for other microorganisms by the ordinary bacteriological methods, so as to determine, if possible, whether tuberculosis is present. It must be remembered that tubercle bacilli may be absent in the urine while the kidney is the seat of tuberculosis, so that the absence of these germs from the urinary sediment by no means proves the absence of tuberculous lesions of the kidneys, but in most cases, when the pyuria is of renal origin, these bacilli are present when the stage of destruction has been reached. Numerous other germs are found in urines of tuberculous kidneys affected with suppurative complications.

If stone be the cause of the pyuria, we may get a crystalline clue to the nature of the malady by the unusual abundance of one or the other organized sediment, but usually this test is not trustworthy unless the crystals be very abundant, indeed.

Portions of tumors, sarcomas, or carcinomas have been found in the urine in cases of renal tumor, and have led to a correct diagnosis. Unfortunately, for obvious pathological reasons, such occurrences are rare, and the urine of tumor kidneys does not show, as a rule, any specially characteristic features.

Having obtained the *full urinary report*, and having considered it in detail, we have, aided by the findings of the physical examination and the history, by this time determined that a suppurative condition exists in the kidney, or pelvis, or both, and that it is probably due to a stone, tumor, tuberculosisis, or to infection without these factors. It now remains to determine which kidney is affected, if only one, and to find out what the condition of the opposite kidney is. The means available for this purpose are cystoscopy, ureteral catheterization, segregation, and exploratory incision.

Cystoscopic Examinaton.—Cystoscopy is certainly one of the most important diagnostic methods in the group of renal disease accompanied by pyuria, for it enables us to tell the state of the bladder, and to exclude positively the presence of vesical disease, such as stone, tumor, or tuberculosis accompanied by cystitis, or to see that they exist in addition to renal trouble. No thorough urological examination is complete nowadays, whether in men or women, without cystoscopy. An examination of the streams trickling from the ureters also tells us whether one or both kidneys are secreting urine, and whether there is any difference in the appearance of this stream, as regards cloudiness, viscosity, etc., or the manner of trickling on one side or the other. Blood, pus, small clots, pieces of mucus, etc., may be seen issuing on one side, the jet may be retarded, or there may be continuous oozing from the ureters instead of the normal interrupted jets. The orifice of the ureter may be dilated, contracted, œdematous, etc.; but, in order to make a thorough study of the working power of each kidney, ureteral catheterization must be resorted to.

Ureteral Catheterization.—Catheterization of the ureters by means of the catheterizing cystoscopes devised by Brenner, Nitze, or Albarran, has now become, probably, the most important means at our command in locating the side on which the renal disease suspected is situated, and in determining the presence of two kidneys and the relative health of each. Unfortunately, there are but very few men in this country, or in any other, who are able to catheterize ureters with success, as the application of the instruments so far devised is an exceedingly difficult one, and a vast amount of special training is required to overcome the inherent difficulties of this diagnostic method. Ureteral catheterization should be employed whenever one is in doubt as to the relative status of either kidney, and should be, by no means, regarded, as it is by some surgeons, as a last diagnostic resort. While in most cases the simpler means of diagnosis will suffice, it is often desirable, nay necessary, to catheterize the ureters in order to confirm the diagnosis. For, it must be remembered, that while we may feel clinically sure that one kidney is involved and the other is not, we never can feel certain of this until the ureters have been catheterized and the urine gathered from each organ has been examined by an expert urinary analyst, nor can we feel sure that a second kidney exists until such catheterization has been performed.

Segregation of the Urine from Each Kidney.—The segregation of the urines from each kidney is a procedure which is more easily applied than catheterization of the ureters, and is claimed by its originators to be as certain, so far as results are concerned, as the latter method. The writer has used the Harris instrument in a number of cases, and it has failed but once, yet it can not be expected to supplant ureteral catheterization, as it is not so exact a procedure in our kidney work, it can not be expected to give accurate results.

The *Röntgen rays* have now been extensively used in renal surgery as a diagnostic procedure, and, thanks to the excellent work of Leonard Johnson, Beck, and others in this country, a great deal has been done to perfect this method, and to make it available for the diagnosis of renal calculi; for very often we have to rely upon the *x*-rays to tell us whether a case of pyelonephritis, with all the signs of renal and pelvic suppuration in the urine, is due to the presence of a stone in the kidney, or whether we must look for other causes. It can only be considered, to my mind, as an aid in confirming a diagnosis, as in a number of cases I have failed to find stones where shadows were plainly seen, and in other cases I have found them when the radiograph showed nothing.

Exploratory Incision.—The exploratory incision is now rarely resorted to, and is never necessary if the ureters can be catheterized. It should, however, be performed whenever a nephrotomy is contemplated, if both kidneys can not be palpated, or both ureters can not be catheterized. Personally, I have resorted to it but once, and then through the median line in front, opening the peritoneal cavity, in a case in which the ureters could not be seen on account of the existence of a contracted bladder and a hemorrhagic cystitis, and I felt that I was not able to tell positively the condition of both kidneys.

In case I were to resort to an exploratory incision again, I think that I would perform it by the posterior route, as the dangers of peritonitis and hernia are less, and it can be performed without changing the position of the patient. In this case, however, the kidney on the supposed healthy side should be examined first, and not after the supposedly diseased kidney has been found to be diseased and removed.

The history, symptoms, and methods of diagnosis in vogue having been gone over, we will proceed to report a few illustrative cases without entering into the long argument of analyzing cases in general, which would be an endless task.

The cases here quoted were chosen from a number of cases operated on during the last few years as illustrative of conclusions arrived at by simple and by more detailed methods:

III. Reports of Cases. Case I.—*Pyelitis.*—Merchant, aged sixty years, had been a delicate child, and had never during his life at any time considered himself robust. He had always attended closely to his business, had raised a large family, and had led a most abstemious life. About six or seven years ago he had begun to notice a frequency of urination that gradually increased and of late grew especially marked at night. For the last few months he had suffered from frequent and painful micturition, which had so increased during the last few days that retention had set in. During these last few days he had also noticed marked swelling of the lower extremities, abdomen, and hands, and a physician who had been called in, had given it as his opinion that he would not live longer than a day or two, and that he was dying of nephritis.

Examination.—Œdema of the extremities, from the feet to the middle of the thighs. Abdomen distended, puffiness under the eyes. Palpation in lumbar region negative, in the suprapubic region the bladder tumor was outlined extending above the umbilicus. A rectal examination showed a prostate twice the normal size, and a large tumor in the pelvis (distended bladder). A catheter was inserted and 22 ounces of urine withdrawn. Five hours later sixteen ounces were withdrawn; then twelve ounces every three hours until his bladder was emptied. The urine examined was dark yellow, specific gravity 1018, no albumin; no casts; urea 1.4 per cent.; few epithelia from the bladder, ureter, and pelvis of the kidney; few pus cells and blood cells. The patient evidently had had a dilated bladder and ureters, and a temporary double hydronephrosis with but a slight degree of infection. He was catheterized every four hours, but the same symptoms continued, the patient evidently having a chronic cystitis and pyelitis. He was then broken into catheter life and enjoyed good health for six months in the country. Until then the case had been one of pyelitis without penal involvement.

On his return, when the cold weather started in, he began to develop pain in his back and tenderness on palpation over the kidneys. Hyaline and granular casts appeared in the urine, together with epithelia from the straight and convoluted tubules. The specific gravity diminished, the amount of pus increased and the amount of urea diminished. He began to develop uræmic symptoms, and finally died of pyelonephritis. The first part of his kidney trouble was a pyelitis. Patients, however, rarely die of pyelitis alone. They either recover, develop complications and die, or else the pyelitis remains chronic for some years.

Case II.—*Unilateral Ascending Pyelonephritis.*—Mrs. A., housewife, aged forty-five years, presented herself, complaining of pain in the right loin for a number of weeks, at times more severe than at others, always dull in character and occasionally lancinating. During this time she had had fever, chilly sensations and sweating. No appetite, indigestion, bowels irregular; loss of flesh.

Examination showed a kidney on the right side large enough to be outlined and tender to the touch. Her uterus and ovaries were found to be normal. The urine examination was as follows: Amount, thirty-nine ounces in twenty-four hours; acid; specific gravity 1026, slight amount of albumin, urea 1.6 per cent., considerable pus, blood, epithelia from the bladder, ureter, renal pelvis, and tubules of the kidney. Hyaline, granular, blood, pus and mixed casts and very few crystals. No tubercle bacilli found in the urine. Cystoscopic examination was unsatisfactory, showing hæmorrhagic cystitis, and catheterization of the ureters could not be performed, as the bladder was very much contracted, holding but two ounces, and bleeding profusely on manipulation. Patient was thin and emaciated. Temperature 101.2° F., pulse 96.

This history pointed to a suppurative process, and the urine showed pus and renal elements. This, together with the tenderness over the right kidney, pointed to disease in that organ. There was a possibility of a calculous nephritis, but it seemed more probably a pyelonephritis due to an ascending infection, especially as the bladder was so deeply involved and contracted. An operation was indicated, but not being able to catheterize the ureters, and, therefore, not knowing the condition of the other kidney, or even its existence, I made an abdominal incision and palpated both kidneys. The left seemed normal, the right enlarged and irregular and nodular. A lumbar incision on the right side showed a kidney with numerous small abscesses, which could be plainly seen in the cortex. The kidney was removed. The patient has made a good recovery, and has been doing well since. The kidney was shown at a society composed of prominent surgeons, and it was a disputed question whether the gross lesions were those of tuberculosis or of an ascending pyelonephritis, but the pathological examination, confirming the the urinary report, showed that the latter was the case. This was a plain case, in which the exact condition that was suspected was found. There were sufficient kidney elements to show the presence of kidney disease. Yet, on account of the cystitis, the ureters could not be catheterized, and the exploratory incision became necessary.

Case III.—*Tumor of the Kidney*.—H——d, traveling salesman, aged fifty years; traumatism of left testis eighteen years ago, causing acute inflammation. Occasionally has had gastric distress, nausea, and vomiting. One year ago had profuse hemorrhage from urethra accompanying urination, and continuing for two or three weeks. Sometimes will go for a month without hæmaturia, and then will notice it for a while every week. When quiet the hæmaturia occurs less frequently. Urinates five or six times a day, and once or twice at night. Pain on the left side of the abdomen. Urine seems light and clear. He complains principally of blood in the urine and pain in the left loin. He is a large, heavy-framed man, looking somewhat haggard, his clothes hanging loosely upon him. He has lost considerable weight.

Examination showed a tumor in the left loin, in the region of the kidney. Very large varicocele on the left side. Prostate slightly enlarged on the left side. Urethra normal. There was half an ounce of residual urine present.

My diagnosis at the time of the first visit, based upon this history, physical examination, and cachexia, was that of a malignant tumor of the left kidney, and it remained only to verify this.

The urinary report was as follows: Specific gravity 1025, acid, reddish-yellow, considerable albumin, urea 2.6 per cent., moderate number of small and large hyaline, fine and coarsely granular pus, blood, epithelial, and mixed casts, and calcium oxalate casts. Numerous blood-corpuscles, often in masses; numerous pus-corpuscles, chiefly isolated. Numerous disintegrated and granular renal epithelia and numerous calcium oxalate crystals, often on casts. Besides this, some peculiar cells were noted, which might be taken for tumor elements.

This showed that the blood came from the kidney, and that the patient had a suppurative pyelonephritis, which might be due to tumor or to stone. In other words, my diagnosis of tumor, which was quite positive on my first examination, was somewhat shaken by the appearance of so many calcium oxalate crystals, alone and on casts, coming from the kidney. There was no necessity in this case of catheterizing the ureters, as the tumor spoke for itself, and there was a large amount of urea in the urine, showing that the other kidney was probably functionating properly. A lumbar incision was made on the left side and a large adenocarcinoma found, and the left kidney removed. The patient made an uneventful recovery, regained his former weight and, most astonishing of all, his varicocele on that side entirely disappeared.

Case IV.—*Tuberculous Pyelonephritis*.—Mrs. F., aged twenty-five years, a hard-working, thin, and unhealthy-looking housewife, who, for nearly a year, had been complaining of frequency of, urination, and of pain in the right side. At first she passed frequently, night and day, large quantities of pale urine, of a low specific gravity. The color, however, gradually grew darker until lately her urine had been thick and quite highly colored, and the frequency of urination had increased. Occasionally she has great pains in her right side, followed by a discharge of viscid urine and a cessation of the pain. At times she has had fever and sweats, which she believed to be malaria, and she has lost weight. There was a family history of tuberculosis, and she had scars of tuberculous glands in the neck.

On examination patient looked cachectic; temperature, 99.8°; pulse, 96; heart and lungs normal. She showed an enlargement of the right kidney, and a tenderness of that organ to the touch. Vaginal examination showed the internal genitals to be normal. Cystoscopy showed a chronic cystitis and urine coming from both kidneys, but more from the left side. Urinary examination showed a specific gravity of 1022, urea 1.8 per cent., moderate amount of albumin, few blood cells, and a considerable amount of pus; hyaline, granular, and mixed casts; epithelia, both from the bladder and kidney, and a large amount of detritus. It was evidently a case of pyelonephritis, and as the urinary examination showed tubercle bacilli, no further examination was made.

The kidney was removed and was found to be greatly changed. It contained a number of so-called tuberculous cysts, filled with pus and detritus. At the time of operation, nephrectomy seemed to be a perfectly proper procedure At the present time, however, I would not remove a kidney diagnosticated as tuberculous unless the ureters had been previously catheterized to show the exact condition of the other kidney. During the last year I had a very similar case in a boy of sixteen who had been running a temperature since entering the hospital. The kidney was enlarged and tender; the urine showed tubercle bacilli and pyelonephritis, the lumbar incision showed a large kidney with numerous tuberculous areas. The kidney was removed. The patient died in eight days of anuria. Autopsy showed that his only kidney had been removed. The kidney was a typical tuberculous one, quite diffusely involved, and breaking down in many places.

Case V.—*Calculous Pyelonephritis*.—Mr. D., a merchant, forty-five years of age, had had several attacks of urethritis between the ages of fifteen and thirty. Twelve years ago he had an attack of renal colic on the right side, lasting for three days. For the past seven years he has had pain and repeated attacks of colic on the left side; occasionally he had fever for a few days at a time; he suffers from indigestion and constipation. Family history negative; has had gout and rheumatism. His principal symptoms were constant pain on the left side and renal colics. Urinates seven or eight times a day, and once at night.

Examination showed the patient to be thin and sallow. Temperature 99.4, pulse 84. His kidneys could not be outlined. There was slight tenderness over the area of the left kidney. The epididymes were indurated; the prostate was of normal size but hard; the urethra showed a stricture 21° F. at four inches.

His urine showed a specific gravity of 1017, strongly alkaline, ammoniacal, trace of albumin, urea 1.8 per cent., occasional blood cells, innumeralso pus cells, mixed with mucus, phosphates, and crystals of various kinds. Bladder and renal epithelia, and occasional granular and hyaline casts; many gonococci. (In ammoniacal urine, only urine freshly drawn shows casts, and if allowed to stand for awhile they were destroyed). This examination showed that the patient had a stricture, a cystitis, a pyelitis, and a nephritis, with the gonococci still present in the urine, having evidently existed there since his last attack of gonorrhœa, fourteen years ago.

It seemed as if his renal affection was an ascending pyelonephritis of the left kidney, following an obstructive cystitis from stricture. This was borne out by palpation of the organ on that side, as it was tender to the touch. The renal colics on the left side, and the amount of phosphatic crystals in the urine, together with the phosphatic cast of the calyces of the kidney, which he at one time passed, led me to think that there might be a stone in the left kidney as well (calculous pyelonephritis). The indurated epididymis and prostate pointed to tuberculosis, but there were no tubercle bacilli in the urine. I determined upon ureteral catheterization, to ascertain the condition of the right, or supposedly healthy, kidney. The urine from left kidney showed chiefly a large number of isolated red blood-corpuscles and numerous epithelia from the renal tubules—a mild pelvic irritation; no casts were found. The urine from the right side showed occasional granular, epithelial, and mixed casts (leucocytes, blood cells, and granular material), innumerable red blood-corpuscles, pus, occasionally in small masses, and granular renal epithelia. This kidney excreted only about one-sixth as much as the other in the same time, and the urine on this side was very much worse. These facts gave another aspect to the case, and it looked as if the right kidney were at fault, with a pyelitis due to calculus, to ascending infection or both, and that the left kidney showed simply the reno-renal reflex, with a slight interstitial nephritis, and, perhaps, a calculus in the pelvis. Many of the red blood-corpuscles present were due to the irritation of the catheter. I, accordingly, determined to have the patient *x*-rayed as the next step prior to operative treatment. The result of the examination was that a stone was found in the right kidney, and was delivered by nephrotomy. This illustrates the importance of the *x*-ray as a deciding factor in influencing operation in these cases, but it does not, by any means, follow from that that it is infallible. Only recently, in a case that showed, on radiography, a stone in the left ureter and another in the right kidney, confirmed by a second exposure, the operation showed that no stone was present in the ureter, and yet the left kidney, which I removed, was almost entirely destroyed by ascending infection from an old urethritis.

CASE VI.—*Calculous Pyonephrosis.*—Mrs. F., aged forty-five years, entered the hospital, saying that she had been suffering for years from malaria and indigestion. Her symptoms had been pain in her right side, usually dull, but sometimes acute and severe and attacks of chills, fever, and sweating, lasting for a day or more and then disappearing to return again after an indefinite period. This had caused her to lose considerable flesh and strength. Recently she had, at times, noticed a swelling on the right side, which was painful to the touch, but which would suddenly disappear, giving her considerable relief. She stated that her appetite was poor, digestion bad, bowels constipated, and that recently her urine, which had for a long time been thick at times, was now oftener of a [illegible] consistence.

The woman was very thin and cachectic. On entering her temperature was 101.4, pulse 96. There was a tumor on the right side, extending from below the ribs to the iliac crest and pelvis, occupying almost the entire right loin. The urine was thick, yellowish-white, neutral in reaction, specific gravity 1020, small amount of albumin; urea 200 grams in twenty-four hours; pus, hyaline, and granular casts, bladder and pelvic epithelia, a large quantity of pus, a few blood cells and some uric-acid crystals.

On the following day her temperature had fallen to 99° F, and the pulse to 82. The tumor was very much smaller, and the urine contained a comparatively small amount of pus. After watching the patient for a few days it was evident that she had pyonephrosis, probably due to calculus, as there was always some enlargement of the kidney, even when it was evidently emptied of pus, while when it was full of pus it was large enough to show that the parenchyma must have been very extensively destroyed. There were no facilities for ureteral catheterization or radiography.

An operation was performed through a curved incision in the loin, and a very large tumor was removed. This, when opened, was found to contain nearly a pint of pus and five large renal calculi. The kidney was merely a bag of pus. The patient died in four days, and the autopsy showed acute cloudy swelling in the other kidney.

CASE VII.—*Pyonephrosis; Renal Retention; Movable Kidney.*—Mrs. M., aged forty-four years. Mother and sisters died of Bright's disease, father of cholelithiasis; gout and rheumatism in members of the family. Well up to twenty years ago, when she complained of frequency of urination. The urine examined by the practitioners attending her at that time, contained pus, showing the presence of cystitis. Two years ago she had an Alexander operation performed for uterine displacement. Shortly afterward she had an attack of pain in the right side, then no attacks for a year, when she had an attack of pain lasting for four hours. Six months later another attack; one month later another. Then she had no other attacks until two weeks before, when she had a severe one, accompanied by hæmaturia. The principal symptom during these attacks was severe pain of a colicky character in the right side, running down to the thigh, besides which there was a continuous pain in the left side. At present, in addition to the above symptoms, she suffers from occasional headaches and indigestion. She urinates ten times a day, but none at night.

The doctor who referred her to me gave me this history, stated that her urine contained blood cells, bladder, and renal epithelia. He also said that her kidney could at times be outlined and at times not. Her condition had been diagnosticated as acute gastritis, gastralgia, cholecystitis, and stricture of the ureter.

Examination showed her right kidney to be movable behind a cushion of intestine. A thickening could be felt on either side of the uterus. The uterus itself had a rounded feel as if it contained a small fibroid, and the cervix had been amputated. It seemed at this examination as if she had pyonephrosis from renal retention, stone, or tuberculosis.

For some time after this the patient was below par, suffering from slight nausea, headache, and indefinite pain, showing symptoms of mild uræmic intoxication. She was passing but twenty-four ounces of urine in twenty-four hours. There was a large amount of pus in the urine. On the ninth day after she was first seen she had an attack of renal colic, the pain being so severe that she fainted twice.

Urinary examination showed the specific gravity to be 1012, the reaction to be acid; contained some albumin; the amount of urea was 150 grains in twenty-four hours; the amount of urine eliminated was thirty-two ounces. Uric-acid crystals, red-blood cells (moderate), pus-corpuscles, renal epithelia from the pelvis and tubules of the kidney and upper layer of the bladder.

After this urinary examination my diagnosis was pyonephrosis and nephritis, probably of the right kidney, due to renal retention and, perhaps, stone. The ureters were accordingly catheterized; one-twelfth as much urine came from the right kidney as from the left. The specimen from the left kidney showed specific gravity 1012, acid reaction, albumin, moderate amount; the amount of urea was 0.7 per cent. Moderate number of uric acid crystals, few pus-corpuscles, epithelia from the pelvis of the kidney, the ureter, and the tubules of the kidney, *i. e.* a mild pyelonephritis. The specimen from her right kidney showed epithelia from the ureter, pelvis, and tubules of the kidney, blood globules, few pus-corpuscles, uric-acid crystals, and connective tissue shreds. The small amount of urine coming from the right kidney showed that it was not doing its share of work, and I concluded that it must be very much impaired, through a chronic nephritis or a hydro- and pyonephrosis or a calculus. Interstitial nephritis evidently existed in both kidneys. No *x*-ray examination was made. The patient was operated upon by lumbar incision, the kidney was found to have a long pedicle, and to be exceedingly small in its lower pole, and very large in its upper pole. It was very adherent to a loop of intestine, the two evidently making excursions together in the abdomen. Palpation of the kidney revealed no stone, neither did it have the appearance of a calculous kidney. The fatty capsule was dissected away, over the convexity of the organ, the capsula propria stripped off over the posterior half of the kidney, and the organ anchored to the abdominal wall. The patient made an uneventful recovery. It remains to be seen what improvement will be derived from this operation, and how much the functional power of the kidneys will be increased.

This was, therefore, a case of movable kidney with transient hydro- and pyonephrosis and chronic nephritis. The right kidney had given rise to clinical symptoms on that side; the organ had been felt then at times, showing a difference in size. The presence of both kidneys had been established by ureteral catheterization, and the right had been shown to have about half the secreting power of the other. The operation showed our diagnosis to have been correct.

In these last cases of pyonephrosis, the kidney was enlarged at times, and the patients had considerable temperature and increased rate of pulse. Such a condition is not necessary, however, and in some cases of typical pyonephrosis, in which only small portions of the kidney tissue remained healthy, and the organ was full of pus, it was at no time possible to outline the kidney during months of observation, and the patient never had an elevation of temperature of more than one degree.

Summary.—I have endeavored to show in this article the train of thought followed by the surgeon in diagnosticating a case in which a renal lesion is manifested by pyuria. For this purpose I have outlined, step by step, the methods of examination employed in modern renal surgery, and have indicated the weight to be attached to each factor as it is brought to light in this examination in determining the seat and the nature of the lesion present. In order to illustrate the practical application of the methods of diagnosis thus outlined, I have added a number of case histories.

In conclusion, I may say, that my experience with clinical problems represented by cases of renal diseases accompanied by pyuria leads me to formulate the following principles as guides to the diagnosis in such cases:

1. Given a case of pyuria, the seat and the nature of the lesion should be determined by all the methods at our command before an exploratory incision or an operative procedure is attempted.

These methods include, in addition to the general and physical examination: (1) Examination of the urine, including cryoscopy and the phloridzin test; (2) Cystoscopy; (3) Ureteral catheterization; (4) Segregation of the urine from each kidney by appliances introduced into the bladder and not into the ureters; (5) Radioscopy.

2. The examination of the patient's urine in such cases should be considered as of the utmost importance and should be intrusted only to men thoroughly trained in this line of work, particularly in the microscopy of urinary sediments.

3. It is possible, by a careful study of the pus, blood, casts, and particularly by a study of the epithelial elements of the urinary sediment to determine the nature of the lesions and the seat thereof in the urinary tract.

4. A renal lesion of suppurative character being found, it becomes necessary to locate it in one or the other kidney, or to determine whether the opposite kidney is present and healthy. This may be done with the aid of cystoscopy, ureteral catheterization, combined with the phloridzin test, and followed by the examination of the urines from each kidney; with the aid of the Röntgen rays, and, if need be, in case of doubt, of exploratery incision.

5. An omission of one or more links in the chain of methods of examination here enumerated may give rise to grave errors in diagnosis, and nephrectomy is never justified when we are not in the position to say that the opposite kidney is present and in good condition on the basis of the tests herein mentioned.

75 West Fifty-fifth Street.

The Importance of the Early Treatment of Catarrhal Conditions of the Upper Air Tract in Children.—Carolus M. Cobb says that nasal obstruction, from whatever cause, leads to disturbances of sleep, to anæmia from lack of sufficient oxygenation of the blood, to malformation of the chest wall, and to various reflex nervous disorders. Mouth breathing, and often the extension of the inflammatory process, cause attacks of bronchitis. Disorders of digestion occur from the swallowing of secretions of mucopus. An inflammatory condition of the nose and throat is a fruitful source of infection of the cervical glands, and many cases of cervical adenitis, now classed as scrofula, are directly traceable to this inflammatory condition. Finally, many cases of general systemic infection are now known to have their origin in either acute or unrecognized septic conditions of the throat. As an illustration, it is only necessary to allude to the reported cases of endocarditis and acute articular rheumatism caused by the products of a tonsillar abscess gaining access to the general circulation.—*Annals of Gynecology and Pediatry.*

THE TREATMENT OF ACUTE DYSENTERY.

By J. DICKSON HUNTER, M.D., Edin.,
AREQUIPA, PERU.

In the Medical Record for May 3 and 10 the subject of dysentery is discussed editorially. With the editor's permission, I should like to make some observations upon the same subject, particularly as to treatment, which may interest some of the readers of the journal who are practising in localities where this disease prevails.

As giving some little weight to the following statements, I may mention that, excluding the time passed in visits to Europe and the United States, I have been a practitioner in Peru for nearly forty years, and that in Lima and Arequipa dysentery is endemic.

Mortality statistics in Peru are not very exact or reliable, but a rough estimate may be made from the following: In this town there is a small hospital, containing 250 beds. The average annual mortality in this hospital is 150. Many of these cases, without doubt, are taken to the hospital when it has become evident to the relatives that the patient is moribund, the reason for this being that, when the patient dies in the hospital, the burial expenses, which are heavy, are avoided. Moreover, many of these cases have been neglected at the beginning of the illness. This leads to my first recommendation; namely, never look upon a case presenting the slightest sign of dysentery as a trivial complaint. True, there are cases which, with a dose of castor oil, or sulphate of magnesium, or of sodium, an enema of linseed infusion with starch and tincture of opium, and being quiet in bed, will get well; but that cannot be counted on. Therefore, I think it more prudent to overtreat a case from the first, and so prevent the disease getting a hold which may be extremely difficult to shake off.

When called to a case I generally at once prescribe ipecacuanha. This drug has proved so curative in the majority of cases that one dislikes trying anything else until that has failed, or there is some decided contraindication. I prescribe 45 grs., preceded by 15 or 20 drops of tincture of opium half an hour before, and a sinapism to the pit of the stomach. This dose is administered preferably in the morning fasting. It is repeated the following morning, or in twenty-four hours. As a rule, in spite of the laudanum and sinapism and the abstention from food or liquid before and for three hours after, considerable vomiting and nausea are produced. There are some patients, however, on whom it does not produce these effects, and nevertheless they are cured. There are others, who are passing dark, very fetid stools, who take it as if it were so much water, no effect being produced. In these cases the prognosis is of the worst, the system seeming incapable of any response to medication.

Instead of giving opium before the ipecac, I have found that a hypodermic of morphine, gr. $\frac{1}{6}$, a quarter of an hour before, acts well in preventing the nausea and vomiting, though it seems as if it caused a contraction of the pylorus, for, even after three or four hours' abstention from food or drink, if the patient takes something, he is almost sure to vomit the ipecac.

The vomited matter is frequently very acid, and for that reason it is useful and agreeable to the patient to make him wash out the mouth with a solution of bicarbonate of sodium after each spell of vomiting. I have sometimes associated the ipecac with the soda, but it does not appear to make any difference in its nauseating or curative effects.

Peruvian practitioners generally prescribe infusion of the contused root of "raiz disenterica" (their name for ipecac), which is especially useful in prescribing, as then the patient does not know what he is going to take, which is often desirable. One of their plans of administering it is to put ʒ i of the contused root in 2 oz. of boiling water at night. In the morning the patient takes the clear, supernatant liquid. The sediment is again treated at night with 2 oz. of boiling water, and in the morning the patient again takes the clear part. This is repeated a third night and morning. Another plan is to put the drachm of contused root in three or four tablespoons of boiling water for fifteen to twenty minutes. Administer the clear fluid at, say, 6 or 7 A.M. At midday the same root is again put in infusion, but this time for an hour, and then the clear fluid is given. The same root is again immediately treated with boiling water, but this time the root is well pounded with a teaspoon and left to infuse for five or six hours, when the clear part is again administered. I have tried both plans and have been satisfied with the results. The clear, supernatant fluid is less provocative of disgust to eye and palate than the powder. Many years ago I tried emetine, and some years ago ipecac sina emetina, but neither of them gave encouragement to continue their use.

Peruvian practitioners give enemata of the strained infusion of 1 or 2 drachms of the contused root. This does not provoke nausea, but I cannot say that I have seen it alone cure a severe case. It may assist, just as copious injections of warm water, say with a little carbolic acid, or boric acid, or even pure warm milk, do good, especially if, immediately on their expulsion, they are followed by a 2 or 3 oz. injection of starch and tincture of opium. Five or 6 oz. of a 1:2,000 solution of permanganate of potassium, preceded by a sodii bicarbonate injection, or an injection of liquor hydrargyri perchlor. (P. B.) ♏xv to an ounce of water are also useful. The starch and opium often takes away, at least for a time, the disagreeable feeling about the rectum and anus. Other things which often soothe the patient are a hot sitz-bath, the water reaching to the lower ribs; bathing the anus with hot water or applying a flaxseed poultice after a stool; also covering the abdomen with hot toasted bran or salt in a flannel bag.

After the ipecac, what is to be done? As a rule, very little. Keep the patient at rest and warm in bed, and attend to his diet. Sometimes there is diarrhœa, which is not unfavorable; should it, however, appear to be more than is good for the patient give either nitrohydrochloric acid with tincture of nux vomica and infusion of calumba, or even chalk mixture, with bismuth, salol, and a little glycerin. In other cases the bowels remain confined, and require a copious enema of mallow, or other emollient, with olive oil.

But suppose the ipecac does not cure the patient, or even makes him worse, as happens in a few cases; or that he so immediately vomits it that little or no curative effect is produced; or that, having passed through other attacks of the disease—dysentery being one of those diseases in which one attack seems to predispose to future attacks—he refuses to take the ipecac, dreading the extreme nausea which it has caused him on previous occasions, what is to be done? In Peru many medical men give an emulsion of castor and almond oils (emulsion de Frank) in small, frequently-repeated doses. There is a remedy used by irregular practitioners which sometimes does good. The interior (omentum) of a fowl is warmed until all the fat is dissolved out; this fat is administered in doses of two to ten or more tablespoonfuls in mallow tisane, or even in chicken soup, and may be repeated in the day. In some of these cases I have tried the sublimed sulphur, grs. xx and dover's powder grs. v every four hours; also the sulphates of magnesium or sodium. The use of these sulphates is comparatively modern, but it is a curious fact that more than thirty-five years ago I knew an old Peruvian physician who had some reputation as a curer of dysentery, and his favorite remedy, especially in cases of chronic dysentery, was a mixture of sulphate of magnesium and manna.

In some of the cases latterly alluded to I have even used resin of podophyllum gr. $\frac{1}{8}$, powdered ipecac gr. $\frac{1}{4}$, repeated every hour or two until bilious stools were produced; these are always of favorable augury. This reminds me that in some cases where the ipecac has failed palliatives may be used for a few days, then a $\frac{5}{15}$ gr. dose of calomel is given at night, and the ipecac given next morning It may then produce its curative effect.

Many of the rebellious cases seem to be more of a colonitis (so-called colitis) than the more common inflammation of the lower part of the bowel. One deduces this from the absence, more or less complete, of the characteristic straining; moreover, on palpating the abdomen the chief pain may be found about the cæcum, or other part of the colon. In some of these I have repeated the ipecac even as many as eight times, and at last the patient may pass a piece or pieces of dirty, gray, very bad-smelling membrane. Immediately after that the stools have lost their dysenteric character, the patients, though extremely prostrated, entering on convalescence. Turpentine is recommended to be tried in chronic cases, but I have found it very useful—in fact, sometimes surprisingly so—in acute cases. In some chronic cases which have lasted months, and when one diagnoses ulceration, the effect of turpentine is so quickly beneficient that one revises the diagnosis. When other remedies fail in acute dysentery try: ℞. Ol. terebinth, ʒ ii; tr. opii., ʒ i; syr. gum acaciæ, ℥ jss; mucilaginous acaciæ, ℥ viiiss. Tablespoonful every two or three hours. After twenty-four or more hours, improvement being noted, reduce frequency. Many people when ill dislike sweets, in that case substitute for the syrup an equal quantity of mucilage. One of my colleagues has such faith in the turpentine that he begins the treatment of an acute case with it. I have found it especially useful in those cases which seem to be aggravated by ipecac.

There is another remedy which I have found useful in similar circumstances, especially when the movements continue greenish and slimy; it is lactic acid. It has been much used in the diarrhœa of children, but I have not seen it referred to as a cure for acute or subacute dysentery. In both of these conditions it may be found very serviceable in doses of 15 ♏., largely diluted, as it is very acid; a little syrup of gum improves it to most palates. At first it may be given every two hours, then gradually reduced to three times a day. Iodoform, in doses of one-third, one-half, or even one grain, with a sixth or more of opium, several times a day, I have seen act well in some cases with severe abdominal pain, other remedies having failed.

The above are the principal remedies I have found of use. Neither the disease dysentery nor the patients are all alike—far from it. For example, some patients present themselves at the practitioners' consulting room who are passing ten or more dysenteric stools a day; they may even be attending to business, and do not look seriously ill. Others, with half that number of stools, are prostrated in bed, and one sees they look bad. Some present always a clean tongue; others, in spite of emetics, purgatives, and strict diet, never have clean tongues. Some complain much of thirst, and beg for ice; others have no thirst. Pain, tenesmus, fever, all may be absent or severe. I have seen a few patients who not only had difficulty in making water, but who passed twenty-four hours without doing so. In these cases I have introduced a catheter, drawing off a small quantity of highly colored urine. Though using a soft-rubber catheter, it has always caused severe, burning pain. In one case the catheter had to be used for ten days, morning and night. The case recovered without any resulting vesical or urethral complication.

What should dysenteric patients eat and drink? For drink, at first boiled water, adding gum when cold, toast and water, water boiled with a roasted apple or quince; ice also may be given if there is much nausea, swallowing small pieces. As to food, during the first two or three days there will probably be very little appetite, but chicken soup, or weak tea with very little or no sugar or milk; arrowroot, if made with guava; that is, guava boiled in water with a little sugar, and then passed through a grater or wire sieve; the arrowroot is then boiled in this water. Afterward stronger soup, even with rice, being, if thought necessary, strained, and a raw egg, beaten up a little, added to the soup when not very hot. Toasted bread, boiled fish, broiled meat, and so on. I may mention that guava, eaten uncooked, is a popular remedy for dysentery, especially chronic cases, in this country, sometimes doing good, but with other patients doing harm. A pamphlet entitled "Contribution à l'étude du Psidium Pomiferum L. par Joseph Khouri Lille," appeared in 1895, eulogizing the fruit, leaves, bark, and roots in the treatment of dysentery.

Once the patient is better he may be allowed very quickly to return to ordinary diet, as the stomach and small intestine are little affected in most cases. In spite of the fact of a microbic cause, one is inclined to believe that cold often prepares the ground for the attack; so those who have suffered and so are predisposed to suffer, should use warm footgear and a wide abdominal belt of flannel or knitted worsted; besides, they ought to avoid the comparatively cold mornings and evenings, which are common in many, especially high altitude, tropical and subtropical regions.

A TABLE OF THE DIFFERENTIAL DIAGNOSIS OF COMA: WITH REPORT OF A CASE OF FRACTURE OF THE BASE OF THE SKULL, INTRACRANIAL HEMORRHAGE, AND COMPRESSION OF THE BRAIN, DIAGNOSED BY SYMPTOMS ALONE; TREPHINING; RECOVERY.

By SINCLAIR TOUSEY, A.M., M.D.,
NEW YORK.

PROFESSOR OF SURGERY AND RECTAL SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; CHIEF SURGEON, ST. BARTHOLOMEW'S CLINIC.

T. C., a boy nine years old, was admitted to St. Bartholomew's clinic on August 27, 1902, about 3.40 P.M., suffering with a contusion of the right cheek and a hæmatoma of the forehead. There was no wound anywhere. He had fallen from a back-yard fence and was brought directly to the clinic. At that time there was epistaxis and vomiting of about a pint of blood. He was somewhat stupid, and his condition suggested the necessity for a most careful examination of the supraorbital and frontal regions; but this revealed no signs of fracture.

During the next hour he became more and more

A TABLE OF THE DIFFERENTIAL DIAGNOSIS OF COMA.

	URÆMIA.	APOPLEXY.	OPIUM.	ALCOHOL.	DIABETES.	EPILEPSY.	HYSTERIA.	SUN-STROKE.	ASPHYXIA	SYNCOPE	COMPRESSION OF THE BRAIN	CONCUSSION OF THE BRAIN
Previous history....	Bright's disease.	Of cardiac or arterial disease, or of injury.	Usually wanting.	Of alcoholism.	Of diabetes.	Of epilepsy.	Female, with menstrual disorders.	Exposure to heat.	Exposure to foul air.	Shock or fatigue.	Of injury. Blood or serum from ears or nose. Subconjunctival ecchymosis.	Of injury
Onset	Sudden. Delirium or convulsions.	Sudden. Coma, then convulsions.	Gradual. Coma without convulsions.	Gradual. Coma preceded by excitement.	Slow. Drowsiness and oppression.	Aura. Sudden convulsions. Cry. Coma.	Sudden. Preceded by Globus Hystericus.	Gradual. Coma with hardly any convulsions.	Slow. Coma with hardly any convulsions	Onset and recovery slow as compared with epilepsy; rapid as compared with the others	Gradually increasing stupor, with remissions. Headache	Sudden. Possibly convulsions.
Urine	Scanty. Albumin and casts.		Reaction of opium (blue with sesquichloride of iron).	High color. Odor and reaction of alcohol (Anstie's test).	Large amount, sweet odor, reaction of sugar.	High color.	Large amount. Pale color.		Normal or suppressed			
Seminal emissions ...						Yes.						
Odor of breath	Uriniferous		That of opium.	That of alcohol.	Sweetish				That of gas and excess of CO_2.			
Œdema .	General. Face waxy.								Of lungs			
Surface .. .	Dry and cold.	Hot on paralyzed side. Face flushed.	Cool and moist. Face pale and cyanotic	Hot and congested on both sides. Face flushed.	Dry and hot. Face, pale. Emaciation.	Dry and hot. Face pale and cyanotic.	Dry and hot. Face flushed	Hot.	Dry and hot. Face blue	Cold, pale and moist. Face pale	Hot and flushed	Pale and cold
Internal temp.	Low.	Low, then high	Normal or low			High.	High or normal	Very high. 110°	Low	Normal or low	Low, then high	Low, then high
Pulse	Strong and full	Slow and full	Normal or slow.	Rapid, full, and strong.	Rapid, weak and small.	Rapid, irregular and feeble.	Rapid.	Rapid and often feeble.	Rapid, weak and small	Rapid and weak. Hardly felt at wrist	Slow and full	Rapid, irregular, and feeble
Respiration....	Rapid, stertorous, and hissing	Rapid, stertorous, labored, and snoring.	Very slow, irregular, and shallow	Rapid, regular, deep, puffing, stertorous.	Rapid and shallow.	Normal or rapid	Rapid and sobbing.	Quiet.	Rapid, embarrassed and shallow.	Weak, but not embarrassed	Stertorous	Quiet and shallow.
Pupils . ..		Unequal and do not react	Pin-head. Do not react.	Normal. Are equally dilated when face is slapped.		Do not react. Dilate after spasm. Lid half open	React. Lid closed.	Contracted.			Dilated and unequal. Lid closed	React. May be large, small, or of normal size
Strabismus		Yes. (See other points).									Sometimes	
Reflexes . ..	Abolished.	Exaggerated on paralyzed side	Diminished				Normal or exaggerated.	Normal or diminished.			Irregular	
Can be aroused.	No. Deep coma	No. Deep coma	Yes, at first. Coma gradually deepens.	Yes. Momentarily by pain.	No. Deep coma	No, but coma is of brief duration.	Yes. Moral treatment cures	No, but coma may yield to treatment	No, but coma may yield to treatment after hours.	Yes, by slapping face or cold effusions	Frequent remissions in early stage. Later cannot be aroused.	Yes. Momentarily by pain
Convulsions.	At onset. Clonic.	After onset of coma. Unilateral, clonic.				Tonic. Then clonic in repeated spasms	Clonic, long spasms alternate with repose.	Hardly any.	Hardly any.		Clonic, in early stages	Yes, in severe cortical laceration.
Rigidity..		(Post-hemiplegic some weeks later.)				Yes. General.	Yes. Opisthotonos.					Limbs flexed. Lids tightly closed. "Cerebral irritability."
True paralysis .		Same side as convulsions, but later.					No. "Paralyzed limbs" move under ether.				Paralysis of [illegible] special senses or hemiplegia	
Bladder	Retention.	Retention	Retention.	Retention.	Involuntary passage of large amount of urine.	Retention.	Involuntary passage of large amount of pale urine	Involuntary micturition.	Retention.		Retention	Involuntary micturition
Involuntary defecation ..								Yes.				Yes
Other points ..		Conjugate strabismus toward side of lesion if above pons. Head also turned to same side. These may be reversed during stage of convulsions		Vomits.		Bites tongue. No recollection of attack.	Hyperesthesia, especially ovarian.		Blood blue	Recalls circumstances of attack.	Strabismus, convulsions and paralysis in some cases, [illegible] lesion.	

stupid, the pupils became widely dilated; there were clonic convulsions of the left arm and leg, both eyes were turned very far to the left, and the head was also turned to the left. At this stage he could not be gotten to answer questions, but he was still able to stand if some one steadied him. Shortly afterward he became entirely comatose and developed complete paralysis of the left arm and leg. Pricking with a needle produced no effect on the left limbs; but he still made defensive movements with the right arm, when the head was again examined for evidence of fracture. Some ecchymosis of the right upper eye-lid appeared, but there was no subconjunctival ecchymosis. After this his condition changed rather rapidly; his pulse became very slow, and every fifth beat was lost altogether; respiration became somewhat stertorous, and he presented the appearance of one about to die.

Based upon these symptoms alone, a diagnosis was made of compression of the brain from intracranial hemorrhage caused by a fracture of the base of the skull. At about half-past five o'clock that afternoon a few breaths of chloroform were given, as there were still defensive movements of the right arm, and an incision was made directly through the hæmatoma of the forehead. There was no fracture there, but on carrying the incision down toward the orbit a triangular piece of bone, about an inch and a half on each side, was found cleanly broken out. Trephining at its apex, this triangle of bone was removed, and there was a free flow of bright red blood from between the dura and the skull; and some few clots were swabbed out from under the margin of the opening in the skull. There was no comminution or unevenness about the fragment; its edges were vertical, and both the inner and the outer table were as cleanly divided as if by a saw. The fragment included the supraorbital margin and part of the orbital plate and part of the vertical plate of the frontal bone. It had not been at all depressed, and the fracture gave the impression of having been produced by quite a diffused force. No sooner had the blood and clots escaped from inside the skull than the boy began to move his left arm and leg, right on the operating table; and half an hour later he was conscious and asked to have the rag taken off. The periosteum was sewed over the bony gap, and the wound was closed without drainage, but as there was still a little intracranial oozing the sutures were adjusted so as to allow the blood to escape into the dressings.

The subsequent course of the case was comparatively uneventful. There were no cerebral symptoms, and no special rise of temperature. There was primary union throughout; and the only bad effects were diplopia, lasting for about a day, and marked œdema of both orbits, lasting for two days. The double vision was to be accounted for by unequal pressure in the right orbit immediately following the removal of its upper margin and part of its roof. Six days after the injury the boy went home, and twelve days after the injury he went to the public school; we put a stop to that, however.

This history may prove interesting as that of the first ward patient at St. Bartholomew's clinic.

The case was one illustrating the differential diagnosis of coma, and furnishes a reason for publishing, for the first time, the author's diagnostic chart of the causes of coma.

103 West Seventy-sixth Street

Hæmaturia.—Tincture of guaiacum, in doses of half a drachm to a drachm, in milk, every four hours, is considered, by Levy, a very valuable remedy in hæmaturia.

EDUCATIONAL LIMITATION OF VENEREAL DISEASES.*

By FERD. C. VALENTINE, M.D.,
NEW YORK.

FORMERLY PROFESSOR OF GENITOURINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE; CORRESPONDING MEMBER SOCIÉTÉ FRANÇAISE D'UROLOGIE; SECRETARY AMERICAN UROLOGICAL ASSOCIATION, AND DELEGATE THEREFROM TO LA DEUXIÈME CONFÉRENCE INTERNATIONALE POUR LA PROPHYLAXIE DE LA SYPHILIS ET DES MALADIES VÉNÉRIENNES; SECRETARY GENITOURINARY SECTION, NEW YORK ACADEMY OF MEDICINE; HONORARY MEMBER, DETROIT MEDICAL SOCIETY; ETC.

The staunchest advocates of the registration and periodical examination of prostitutes must concede that the dissemination of venereal diseases is thereby but feebly combated. The very exceedingly small effect is evident in many ways, notably in the overcrowding of the offices and public clinics of genitourinary specialists.

The inefficacy of registration and periodical examination is due principally to two facts, namely:

1. A prostitute can become infected and transmit the infection to many men during the intervals between examinations.

2. The clandestine prostitute, the most dangerous and most numerous of bawds, can disseminate venereal disease wholly without restraint under the best system of registration and examination, which she escapes.

These facts alone show official registration and examination entirely inadequate for the accomplishment of the ends for which they were devised. Moreover, as this system of dealing with prostitution gives a false sense of security, it really panders to vice. And, furthermore, its inefficacy prejudices some well-meaning, but partly informed people against anything and everything done to limit the ravages of venereal diseases. The influence of these people is not small, as the history of this matter, especially in Great Britain and the United States, has shown.

Granting, as calm consideration must, the insufficiency of the methods employed, are we right to entirely condemn those that prevail in many European countries? It seems rather that until a better, more effective system is evolved, it were wiser to endeavor to improve upon the one that exists.

It is not intended to even refer to the vast literature that bears upon the subject, nor to submit theoretical or polemical considerations. No other purpose actuates its presentation than to briefly, but crudely, offer a plan which, in our present state of knowledge, may tend toward the desired end.

Before submitting the project even in its crudity, it is necessary to offer some facts regarding the prostitute:

1. Females given to a lewd life, *i. e.* to promiscuous sexual intercourse, are not made prostitutes by anything except the innate tendency thereto. This is denied by many excellent writers, notably Minod, in a brilliant paper published in the transactions of the first congress. He, like others of similar opinion, attributes the existence of prostitutes to man's lust, to social and economic conditions, to lack of proper moral training, and to the law of trade which creates a supply where there is a demand. Careful study of the question, however, shows that man's lust cannot create a prostitute; in fact, no man can make a girl a public or clandestine bawd; social and economic conditions, lack of proper moral training have no important bearing on the matter, for the lowest, vilest slums contain many starving, but rigidly virtuous women, while all ranks of

---

*Read before la deuxième Conférence Internationale pour la Prophylaxie de la Syphilis et des Maladies Vénériennes, Bruxelles, September 1-6, 1902.

society contribute their quota of prostitutes. The allegation of a balance of demand and supply becomes absurd when one observes everywhere that the supply of prostitutes vastly exceeds the demand. The fact seems to be that degeneration is the cause of prostitution.

2. History published and otherwise transmitted, contains not a single instance of a prostitute reformed, or who after the alleged reformation, adhered to a virtuous course.

3. All prostitutes, public and clandestine, are menaces to the health and morality of the community.

4. As in diseases of the individual or of the community, the remedy therefor is revealed, partially at least, by the tendencies of the disease. The tendency of prostitutes to congregate in certain districts is an aid to the plan about to be offered. The ill-directed efforts of some misguided persons to disperse prostitutes from their usual haunts has but one result, viz., to infect erstwhile respectable parts of the community with all the corruption, vice, and disease, from which they were free.

5. The prostitute, public or clandestine, is a worse menace to the weal of the community than is a person affected with tuberculosis, smallpox, yellow fever, the bubonic plague, homicidal mania, or a cur suffering from hydrophobia. Provisions are continually made to protect the people from the diseases mentioned, but public sentiment as yet frowns upon radical measures to limit, while it never can abolish, the worst of all economic and pathological conditions—prostitution. Every moment of the prostitutes' life is devoted to the demoralization of individuals and the dissemination of disease.

6. It is the experience of every specialist in genitourinary diseases that the majority of patients were infected because of ignorance of venereal diseases and their possible consequences; or when under the influence of alcoholic intoxication, or in the imaginary safety (but really greater danger) of relations with a clandestine bawd. That ignorance of the character and consequences of venereal diseases is not always the most frequent cause of their acquisition, is proven by the large number of well-educated physicians who are obliged, by their own venereal ailments, to consult genitourinary specialists.

The preceding postulates suffice to indicate the proposition I beg to submit:

1. That a certain district or districts be set apart for prostitutes, into which district or districts no person under twenty-one years of age shall be allowed to enter; and that any person of either sex violating this prohibition be arrested and imprisoned until the age of twenty-one years is attained.

2. That no carriages of any kind be permitted to enter the prostitutes' districts.

3. That no intoxicating liquor of any kind be given away or sold within the limits of these districts or within ten streets in every direction leading thereto.

4. That no person under the influence of liquor be permitted entrance.

5. That no person living in one of these districts have coitus anywhere else than within her district, under pain of protracted (say, five years') imprisonment; which punishment shall be the same for the person with whom such coitus is had.

6. That all approaches to the prostitutes' districts be guarded by officers especially trained for the purpose.

7. That any offense punishable criminally, shall, when committed within these districts, be visited with double the penalty provided therefor by existing laws.

8. That no person be allowed to enter the prostitutes' districts without having received the following or similar circular from the guards in attendance at the approaches:

WARNINGS TO THOSE ENTERING THIS DISTRICT.

The women living in this district lead immoral lives; to come near them will corrupt your morals and destroy your self-respect.

To have sexual relations with any of these women, exposes you to very painful and life-endangering diseases, which may be transmitted to your future wife and children, rendering them mentally and physically defective.

A prostitute presenting a physician's certificate of health, proves thereby only that she *was* in health when examined. She may have contracted a dangerous disease within a few minutes after the examination.

To allow yourself to be kissed by a woman in this district, is just as dangerous as to have sexual intercourse with her.

The fact that a prostitutes' genitals appear clean and present no discharge, does not prove her to be free from gonorrhœa. The absence of this disease can be established only by a very complex, scientific examination.

To eat with a fork or spoon, or to drink from a cup or glass, which may not have been thoroughly cleansed after a prostitute has used it, may transmit syphilis, with its most horrible consequences, to you, your future wife and children.

If, with the knowledge of what little has been told you herein, you will risk your health and life, you must endeavor to protect those near and dear to you, by the following precautions:

Remember that the use of a cundom is no reliable protection against venereal infection.

Before sexual intercourse, drop a tablet of mercuric bichloride 0.5 into a basin of clean water.

Put, at a convenient place, a 30-gram bottle containing a fresh solution of protargol 4 per cent. in glycerin (Frank). Instead of a cork, have the bottle stoppered with a well-fitting pipette and well-working soft-rubber top.

Immediately after sexual intercourse, and before the erection has entirely subsided, urinate, and then rest the penis in the left fingers, the thumb on top of the head of the organ. Press the thumb downward upon the meatus (mouth of penis). Remove the pipette from the bottle of protargol solution and let two or three drops thereof fall within the meatus.

Thereupon thoroughly wash the entire genital organs with soap and water in which you have dissolved the mercuric bichloride tablet.

In fresh, preferably hot water, thoroughly wash your hands with soap, so as to reduce subsequent danger of infection to your eyes. If they become infected, you may become hopelessly blind within forty-eight hours.

The protargol solution and mercuric bichloride tablets can be bought very cheaply at any pharmacy.

The methods advocated are not guaranteed to protect you absolutely from venereal diseases; they can do no more than reduce your chances of infection.

Patented, advertised, or secret preparations offered for the prevention of venereal diseases must not be employed. Their sole purpose is to make you pay high prices for unreliable preparations.

A circular, embracing these ideas, but better worded to meet all grades of intelligence and education, would serve for the post-graduate instruction of the public—the only available means of combating that ignorance which prevails everywhere concerning venereal diseases.

Naturally, the plan submitted can do no more than contribute to limiting the spread of venereal diseases. No matter what is done toward this desirable end, legislation, preventive and punitive measures must fail to reach clandestine prostitutes. They are and always will remain the most active disseminators of infection. Although conceding the fact, it is not accepted as having any force as an argument against the adoption of a system that will control, at least in a measure, the one manageable source of the propagation of venereal diseases.

For the sake of emphasis it may be permissible to recapitulate, synoptically, the ideas submitted:

A. *Preliminary Education.*—The author's views on this subject have been detailed in another effort.*

1. Sufficient of the physiology and pathology of the genitourinary apparatus should be taught, in institutions for higher education, to convey to students the dangers of genitourinary diseases to themselves and to others.

2. Similar instruction should be given in schools attended by boys at the age of puberty.

3. No man who has ever had gonorrhœa should be allowed to marry until it is proved by a physician that he can not infect his wife.

4. Regular physicians should be elected, by their societies, to deliver evening lectures to the public on genitourinary diseases.

5. Every father should be taught to warn his sons of the dangers of genitourinary diseases. When from incompetence or delicacy the father can not or does not wish to do this, the family physician should discharge that duty.

6. Every medical society should elect its most competent member to write at least one article on the subject, worded for laymen's comprehension, and to be published under the auspices of the society.

That the essential parts of these suggestions are feasible, is proven by the public teachings established in several institutions, notably, among them, at Professor Lassar's Clinic in Berlin.

B. *The Segregation of Prostitutes* would free reputable neighborhoods from the evil influences, bad example, demoralization, and infection of this social disease. It would also be of assistance in the enforcement of the proposed laws, and likewise it would tend to suppress assignation houses, which are nothing but conveniences for clandestine prostitutes, the worst disseminators of venereal diseases.

C. *Periodical Examination.*—The concentration of prostitutes in districts set aside for them would facilitate examination as to their ability to infect others. Such examinations should be made every day, as an approach to effective work. That it cannot be more than an approach has been elsewhere discussed.†

D. *Circularization* would serve as a species of postgraduate education, which would warn men against the dangers they incur.

This outline of a project is offered in all its crudity, under the conviction that the wise and learned men who constitute this Congress will find in it an honest desire to at least humbly contribute to their labors.

31 West Sixty-first Street.

Non-Microbian Germ Diseases.—Views as to infectious diseases have undergone a considerable change since the germ theory of disease was first propounded. A writer in the *Revue Scientifique* of August 2, quoted in the *Literary Digest*, calls attention to this fact, and says "Only a few years ago the notion of infection was strictly limited to the idea of microbes, and all infectious diseases were attributed to the action of microbian germs. Infections provoked by organisms having no relationship with the microbes, had, it is true, been observed, but these organisms were classified in the same group with the microbes, and were described under names implying connection with these latter organisms. Thus the history of the parasites of actinomycosis, of madura foot, of the farcy of cattle, etc., occurs in most treatises on bacteriology, and even the parasite of malaria is sometimes to be found there under the name of bacillus malariæ. Of late, however, observations have been multiplied of true infection produced by divers definite organisms that have no possible relationship with microbes. To mention only vegetable organisms, it will be sufficient to note certain mucorini, most of the blastomycetes, various species of plectascinea, etc. As we know, the seat of these parasites is very variable. A certain number are localized in the integuments, developing on the surface of the skin, penetrating into it more or less deeply, and even invading the hair, nails, etc. But others penetrate into the interior of the organism, taking up their abode either in the mucous surfaces of the digestive apparatus or in the respiratory organs, or they may enter other systems through the blood, and then may give rise to real generalized infection. The various diseases due to these fungi have a very complicated pathology, of which, we understand the causes better than the symptoms, and whose means of cure are yet very insufficiently developed."

Smallpox and the Weather.—In a report on the outbreak of smallpox in the borough of Poplar during 1901 and 1902, Mr. F. W. Alexander, the medical officer of health, argues that there is a connection between the incidence of the disease and certain meteorological conditions. With this object in view, he has prepared a chart containing five curves showing simultaneously (1) the weekly sum of hours during which the sun is above the horizon; (2) the weekly sum of hours of registered sunshine; (3) the mean weekly temperature of the air; (4) the mean weekly degree of humidity, and (5) the number of cases of smallpox notified week by week in the administrative county of London from July 14, 1901, to August 30, 1902. According to this chart the climatic conditions under which smallpox was most prevalent appear to be (1) absence of sunshine; (2) presence of the sun above the horizon for less than eighty hours per week, *i. e.* less than eleven hours per day; (3) temperature of the air below 50° F., and (4) humidity above 75°—the saturation point being taken as 100.—*Lancet.*

Principles of Sanatorium Treatment.—In selecting a suitable case for sanatorium treatment, it is well to remember what hygienic management seeks to secure: (1) The removal of the patient from fresh invasian by the tubercle-bacillus, and separation, as far as possible, from all influences aiding in its introduction; (2) The establishment in the patient of processes of repair and the development of the highest powers of resistance. To this end the instruments employed are: (1) Continuous exposure to fresh air; (2) Free access to sunlight; (3) Regulated rest, (4) Controlled exercise; (5) Abundant feeding; (6) Obedience to hygienic requirements; (7) Strict medical supervision.—Dr. T. N Kelynack.

THE SERUM TREATMENT OF ACUTE AND CHRONIC RHEUMATISM.

It is natural that with the discovery of a microorganism probably pathogenic for rheumatism an attempt should speedily be made to produce a specific serum for the treatment of the disease. Such an attempt has been made by Menzer, who gives an account in the *Zeitschrift fur klinische Medicin*, Nos. 1 and 2, vol. 47, 1902, of his progress in the development of a system of serum therapy for acute and chronic articular rheumatism. In spite of the advances he has made, the author emphasizes the fact that the method is not yet perfect, and has limitations, but he claims that its advantages are no less distinct and certain. It is particularly to be understood that the aim of the treatment is not to abort or cut short acute articular rheumatism, but to afford such potent aid to the organism as to render it able to cope with the disease and to throw it off more readily. The frequent relapses observed in the course of treatment with the salicylates appear to be obviated, or at least made the exception, while recovery from the endocarditis is also greatly facilitated.

To understand the author's theory of treatment, it is necessary to consider his view of the etiology and course of the disease. He bases his theory upon the assumption that, under certain conditions of constitution, weather, etc., the circle of lymphatic tissue which guards the pharyngeal region becomes permeable to the microorganisms habitually present. These overcome the protective agencies opposed to them, and, reaching the circulation, cause metastatic lesions in susceptible organs. In this case, as in many other generalized bacterial invasions, the *loci minoris resistentiæ* are the synovial membranes of the joints, the serous membranes, and the endocardium. The organism, at first prostrated, speedily overcomes the invaders free in the blood current, and then seeks out their separate *dépôts*, in order to render these harmless as well. The reaction of the organism to this process is evidenced by the typical symptoms of local congestion, swelling, and pain, *i. e.* the joint symptoms and endocarditis represent, not the infection, but the effort of the body to overcome it.

The underlying principle of Menzer's method now becomes apparent. Streptococci obtained from the tonsils of patients having acute rheumatism were isolated and used for the preparation of pure cultures. These were injected into animals, and the antistreptococcic serum resulting from this method of immunization was used in the treatment. On injecting it into patients having chronic rheumatism, a local reaction, consisting of swelling, redness, and heat, was caused in the diseased, but not in the healthy joints. The author interprets this as evidence of the assistance to the body's dormant powers of resistance furnished by the serum. In acute cases a similar series of events is observed. The local symptoms are at first aggravated, but subside rather more speedily than is usually the case, and the defervescence, once occurring, is permanent. The action of the serum differs from that of diphtheria or tetanus antitoxin in being primarily bacteriolytic, though it probably has some antitoxic properties as well.

As regards practical results, it seems a little early for predictions. The author's published cases fully justify his not exorbitant claims, but their number is still small, and sufficient time has not elapsed to permit definite statements as to the liklihood of relapses. The method appears to be directly contraindicated in cases of hyperpyrexia and extensive pleural or pericardial exudate. The chief desideratum is the development of some standard by which the strength of the serum can be measured, and this the author hopes to accomplish by a comparison of the hæmolytic strength of blood and of blood plus serum.

LEGISLATION WITH REFERENCE TO SMALLPOX AND VACCINATION.

Dr. Samuel W. Abbott of Newton Centre, Mass., read at the annual meeting of the Massachusetts Medical Society, June 10, 1902, a paper on this subject. In this paper he gives an epitome of the legislation with regard to smallpox and vaccination which has been enacted in Massachusetts. Many of the statutes of this State, now in existence, bearing upon the subject, date from 1701, 1776, 1792, and 1797, and were the outcome of serious epidemics. Then came the discovery of vaccination, with further legislation in 1809, and later enactments upon this same subject.

The existing laws relating to smallpox and vaccination in Massachusetts seem to be fairly comprehensive and sufficiently stringent. With regard to notification, the following five kinds of notice are required by law in each case of smallpox: (1) By the physician to the local Board of Health; (2) By the householder to the Local Board of Health; (3) By the local Board of Health to the local School Committee; (4) By the local Board of Health to the State Board of Health; (5) By the State Board of Health to the State Board of Charity.

With regard to hospitals, the writer says: "Several provisions now exist in the statutes of Massachusetts for the establishment of hospitals, either temporary or permanent, for the reception of persons ill with smallpox. The emergency has arisen more urgently in the present epidemic than ever before, in consequence of the increasing density of the population." There are in Massachusetts at the present time about fifty cities and towns, each having over 10,000 inhabitants. By a report of the State Board of Health of 1890, it appears that about half of these places only had any provision whatever for the reception of persons ill with smallpox, and of these several were merely old-time "pest-houses" so-called, which were inadequate to fulfill the demands of an epidemic of such proportions as the past season has witnessed. This epidemic has stimulated a few more cities to make provisions of this character, but there are still several large towns and cities which are entirely unprovided for such an emergency.

The Massachusetts laws relating to vaccination require: (1) A parent or guardian who neglects to cause his child or ward to be vaccinated before child or ward attains the age of two is subject to a penalty of $5 for every year during which such neglect continues. (2) By an act of 1855, the local Board of Health must "require and enforce the vaccination and revaccination of all the inhabitants," if, in the opinion of the board, it is necessary for the public health and safety. Every person over twenty-one years of age, not under guardianship, who refuses or neglects to comply with this requirement is liable to a penalty.

Dr. Abbott points out that the chief defect in this law is that it recognizes a false principle in sanitation. The ideal community, so far as vaccination is concerned is not that population in which "the public health and safety" requires vaccination at irregular times and seasons, on the eve or in the midst of great epidemics, but a community in which vaccination and revaccination are constantly and uniformly practised, year by year, upon all young children and upon older children at the end of a definite period—say, of ten or twelve years.

The law relating to vaccination of school children in Massachusetts has recently been amended, so that, although still somewhat defective, it answers its purpose fairly well.

Dr. Abbott thinks two points are very clear with regard to infectious diseases and smallpox and vaccination; (1) The necessity of sufficient laws in all countries relative to infectious disease prevention; (2) The necessity of careful enforcement of such laws.

In those countries in which strict regulations regarding vaccination and revaccination have been rigidly enforced—witness Germany—smallpox has become almost unknown. On the other hand, in these countries in which the laws on the matter are lax or inefficiently carried out—witness Great Britain, and though perhaps to a lesser extent, the United States smallpox is more or less rife. Regardless of the captions of the antivaccinationists, the community at large must be protected against smallpox. It has been conclusively proved that vaccination affords such protection, therefore the method should be made universal and compulsory.

CHRONIC SUPPURATION IN THE FRONTAL SINUSES.

The always unpleasant, and sometimes dangerous, disease, chronic suppurative inflammation of the frontal sinuses, is the subject of an interesting paper by Lack in the *Edinburgh Medical Journal* for June, 1902. Most of the article is devoted to the subject of treatment, which is really the most important consideration. Surgeons are not agreed as to whether suppurative processes in these cavities can and should be treated only by intranasal methods, or whether it is necessary to have an external opening in order to maintain efficient drainage, without which nothing good can be accomplished. It is generally admitted that a certain amount of relief can always be obtained by some intranasal method of drainage, but many deny that a real cure can be thus effected. Lack believes that it is a proper general rule to try intranasal drainage in all cases first, and he points out that this must be very efficient in order to offer any prospect of success. To insure efficient drainage it is, as a rule, necessary to do some sort of an intranasal operation, such as removing a portion of the middle turbinate bone and opening the ethmoidal cells. At the same time all sources of obstruction originating in the mucous membrane, such as polypi and hypertrophic masses, should be removed. When it seems desirable, careful attempts may be made to wash out the suppurating sinus from the nose, but no force should be used, and the fluid employed should be salt-solution, or the mildest kind of antiseptic used warm. Strong antiseptics, or fluids forced in and prevented from escaping, may cause serious trouble.

When the methods thus described prove inefficient and important symptoms persist, we shall be compelled to adopt more radical measures, depending on the pathological conditions and the anatomical conformation in each case. These radical operations involve opening the sinuses from the outside and attempting to get obliteration in some way. When the sinuses are not very large, and the bone is free from disease, success is often prompt and deformity slight, but when the bone is already carious or perforated, or when the sinuses are unusually large, the operation must be much more extensive, and the deformity often very marked. The latter is not such an important consideration as is the removal of all infectious material and the establishment of aseptic conditions, since, if necessary, it can be removed by a subsequent plastic operation. After the suppurative process has entirely ceased, and the wound is healed, there is, unfortunately, usually an ugly, depressed, and contracted cicatrix, and the surgeon is often called upon to make an effort to restore the patient's appearance to a semblance of the normal. Under such circumstances some kind of a plastic operation must be attempted, the method depending largely upon the character of the deformity. It is usually necessary to excise the cicatrix and to get a flap from the forehead to cover the area thus produced, but to obtain success in this way provision must be made for filling the cavity left by the obliteration of the sinuses in such a way that the depression will not recur in a short time. To attain this end, use has been made of periosteum, and even of a thin shaving of bone, with moderate success, and the employment of various foreign substances, such as silver or hard rubber, has been suggested. All these methods have given a fair proportion of success in handling a surgical condition at best refractory. Recently, a method of injecting sterile melted paraffin under the skin, to fill out and obliterate certain facial deformities, has been introduced with considerable success, and it is probable that the method would prove very useful in the cases we are describing, after the cicatrix from the suppurative process has been excised. Experiences so far have shown that the paraffin is entirely nonirritating, and may be used with safety in considerable quantity. It might also be possible to use one of the plastic substances employed by dentists. A number of cases have been reported of such successful use under the skin.

THE BANE OF POLITICS IN HOSPITAL MANAGEMENT.

At the fourth annual conference of the Association of Hospital Superintendents of the United States and Canada, held recently at Philadelphia, a discussion took place on "The Relation of the Hospital to the Body Politic." The subject had been referred to a committee of which the Honorable John Fehrenbach of the Cincinnati Hospital was chairman, and who pointed out the frequency with which the privilege accorded the State of sending a limited number of patients to be treated free of charge, in consideration of partial support from the State Treasury in the form of appropriations, is abused by members of the Legislature making the appropriation. Such a state of affairs not only operates unfairly upon the taxpayer of the State and works injury to the medical profession and injustice to the hospital, but it also tends to demoralize those selected to receive the State's bounty. Mr. Fehrenbach states correctly that "Experience has demonstrated that wherever politics has entered the portals of a hospital it has not been for the benefit or welfare of that institution, nor for the benefit of the political party that attempted to exercise control. On the other hand, where politics does not attempt, or is not permitted, to exercise control of institutions organized for the sole purpose of succoring the sick and the hurt, and where honesty, efficiency, and merit alone make the tenure of those employed secure, such institutions are assured of the very best service and the patients of the best care."

Dr. Walter Lathrop of the State Hospital for Injured Persons at Hazleton, Pa., dwelt upon the evil resulting from changes in boards of managers or trustees in State hospitals due to political influences and without due regard to the competency or ability. Although in the State of Pennsylvania appropriations for hospitals must receive the recommendation and approval of the Board of Public Charities, politics and political methods, nevertheless, play a not unimportant part in securing State funds in this way. While the board strives to deal justly in every instance, it is known that the less scrupulous hospital makes application for an excessive appropriation, knowing that it will be awarded less. On the other hand, the institution conducted on a higher ethical plane asks only for a modest appropriation, and in many instances fails to get even that.

TRACHOMA IN NEW YORK.

The importation of diseases peculiar to the class of immigrants which, at the present time, are coming into this country, constitutes a serious menace to the health of the community at large. Of course, any case of grave infectious disease is strictly denied ingress, but there are certain complaints of an infectious nature which, while not in themselves dangerous to life, are, nevertheless, so troublesome and obstinate that those suffering from them are decidedly not desirable immigrants. The most infectious of such affections is trachoma.

On Friday, October 31, a conference was held between eye specialists of New York City and Commissioner Lederle of the Department of Health, when the subject of the increasing prevalence of trachoma among school children was exhaustively discussed. It was pointed out at this conference that the ends of lead pencils, when rubber tipped, are especially liable to communicate the disease when used by pupils who sit at desks side by side, or in the old type of benches made for two or three. Trachoma is common in Egypt, Russia, and in certain parts of Eastern Europe, and flourishes and luxuriates among filthy surroundings. According to the New York *Herald*, November 1, its prevalence in the public schools is so great that about twenty experts were called before Commissioner Lederle at the aforesaid conference, on the grounds of their civic and humanitarian duties as such, to consider the situation. President Burlingham of the Board of Education demanded the speediest and most thorough means of treatment known to medical science, which, while relieving the distress of one, should not endanger the health of another, and, while conserving the health of all, should not interfere with the education of the original sufferer. To this problem, says the *Herald* correspondent neither he nor Commissioner Lederle obtained any satisfactory answer from the experts assembled, and it was intimated by Commissioner Lederle that further conferences might be called to consider details of this danger.

Since the beginning of the school year about fourteen thousand pupils have been excluded from school; of these, 6,667 were suffering from eye trouble.

In the first place, it would appear as if the situation were sufficiently grave to strictly prevent all immigrants suffering from trachoma from landing in this country. Next, if children afflicted with the complaint are to continue their education, they must be isolated, and third, they must be effectively treated and cured before being allowed to attend school in company with other children. Indeed, in order to completely stamp out the disease, its victims should be entirely kept apart from healthy persons.

THE CITY OF THE FUTURE.

There are a few enthusiastic philanthropists who hope to see the day when towns will be constructed and reconstructed, so that the inhabitants may live under the most favorable conditions of health, and who are even now working with this object in view. When that time comes rookeries and narrow streets will be known no more. Sanitation will be as perfect as human ingenuity can make it; water will be pure and plentiful, and there will be numerous parks and open spaces.

In the *Independent*, October 16, Poultney Bigelow has an article entitled "The Worship of Hygeia," in which he describes a congress of mayors and medical authorities who met in Munich for the purpose of comparing notes on the best means of making cities pleasant and wholesome to live in. "This society," he says, "is the Deutsche Verein für Oeffentliche Gesundheitspflege, which was organized shortly after the founding of the Empire, holds its sessions annually in different parts of the country, and counts within its ranks the ablest Germans interested in the many questions which modern citizens are called upon to solve. The supply of pure water, the disposal of sewage, the erection of public markets, control of parks, watering streets, management of train lines—every subject from the microbe to a tall chimney, from public baths to automobiles, is discussed. The great value of this congress lies in the fact that the people who did the discussing were not merely men of the library and the microscope, but were, to a large extent, men of practical experience and clothed with responsibility. They were either chief magistrates of cities or hydraulic engineers, architects, chemists—in short, men familiar with certain phases of modern municipal requirements."

The most effective way to kill or to scotch tuberculosis, and to prevent the spread of infectious diseases, is to enable the dwellers in a city to live in a healthy environment. So long as there are overcrowded, dirty, and insanitary houses, so long will disease originate and spread. Measures to promote the physical well-being of the inhabitants are far more needed in the large, industrial cities of Great Britain and of this country than in a city like Munich, which is excellently situated, and comparatively free from the unhealthy surroundings which manufacturing brings. If a crusade were inaugurated against the conditions which prevail in the lower sections of New York and London, for instance, an incalculable amount of good would be done for the community at large. Munich will serve as an object lesson of what can be brought about by intelligent sanitary reforms effectively carried out.

The Negro as an Industrial Insurance Risk.

The Spectator for September 11 and 18, 1902, contains an article by Frederick L. Hoffman, statistician of the Prudential Insurance Company of America, with the above title. The article renders it evident that legislation requiring equal premium rates for whites and blacks is unjust; only less unjust than would be a law requiring no discrimination in rates on account of difference in age. Massachusetts, Connecticut, Ohio, New York, Michigan, New Jersey, and Minnesota now have such laws. Sentiment and political exigencies apart, the whole question evidently comes down to this: Do whites and blacks, as a matter of fact, exhibit, at equal ages, a difference in longevity? The author shows from the figures of the Census of 1900 that in the "registration area" (States and cities which register accurate statistics) the difference in mortality is marked. Thus, assuming the mortality for the whites as unity, and combining his first two tables, we get the following ratios for the mortality of the negro:

AGES	MALES	FEMALES
0–4	2.35	2.44
5–14	2.19	2.55
15–24	2.77	2.57
25–34	2.02	1.93
35–44	1.79	2.02
45–64	1.64	1.77
65	1.32	1.22

A second interesting comparison is that by diseases, which, the same plan being used, yields the following ratios:

Malarial fevers	0.72
Typhoid	2.08
Influenza	1.36
Diarrheal disease	1.65
Consumption	2.80
Pneumonia	1.92
Nervous diseases	1.44
Heart disease and dropsy	1.61
Urinary disease	1.58
Cancer, tumor	0.72
Liver disease	0.92

If these were not the Census figures over a wide area, one might wonder at the first item. Certainly it reverses former ideas, that the negro was less susceptible to malarial disease. All this shows the inutility of such legislation as that of which Mr. Hoffman complains. It does more—it shows its futility, for naturally the life insurance companies simply cease to bid for such risks. This settles the evil partially, at any rate, as far as the companies are concerned, but it practically leaves the negro out of the manifold benefits offered to-day by life insurance. But then, this is the age of sentimental legislation.

The Immigration Menace.

The annual report of the Commissioner-General of Immigration has recently been published. Of the 648,743 immigrants who landed in the United States during the past year 466,369 were males and 182,374 females. Italy furnished 178,375, an increase of 42,379 over the number for the preceding year; Austria-Hungary, 171,989, an increase of 58,599, and Russia, 107,347, an increase of 22,090. Ireland showed a decrease.

The portion of the report, however, which will particularly interest medical men is that which refers to the importation of disease by means of alien immigration. Many of the Russian and Austrian poor who are flocking to this country are afflicted with extremely infectious, though not especially dangerous, diseases. Mr. Powderley, a short time ago, drew attention to the introduction and spread of trachoma on a wide scale by this class of immigrants, and the matter was treated editorially in the Medical Record. The New York Health Board has since been concerning itself with the subject, and is at the present time taking steps to prevent the dissemination of trachoma among school children.

The Bureau of Immigration, in its report of last year, expressed its confidence in the careful examination by the United States Marine Hospital surgeons as a means of checking the inflow of diseased aliens to American soil. Unfortunately, such does not appear to have been the case, for the report in this connection reads as follows:

"The increase of immigration has been not quite one-third over that of 1901, but the comparative increase of diseased aliens for the same period has been more than two to one. The same races which exhibited the largest number of diseased persons last year maintain their preeminence in this respect for the year under consideration. These figures show conclusively the necessity for legislation which shall inflict upon transportation lines, which have the means of protecting themselves from the effect of a violation of the law by competent medical inspection at the port of foreign embarkation, a penalty proportioned to the gravity of the risk to the health of the American people for bringing diseased aliens to ports of this country."

The time is ripe for legislation to mulct the steamship companies in substantial sums for neglecting to insist upon thorough medical examination on the other side of all would-be emigrants to this country. Such a measure would have the effect of quickly decreasing the number of disease-stricken persons, who now appear to land on these shores without let or hindrance.

Diseases Allied to Yellow Fever.

The researches undertaken by the United States Army medical officers into the causation of yellow fever in Havana and neighborhood, have resulted in a flood of fresh light being thrown upon that disease. No one disputes now that the mosquito is a prominent factor in the spread of yellow fever, although there is not universal agreement as to it being the sole means of disseminating the malady.

Mr. James Cantlie, at the meeting of the British Medical Association held this year at Manchester, discussed the matter at some length. He reviewed thoroughly and highly praised the work done by the United States' Commission with regard to the etiology of the disease, and considered that the conclusions respecting its pathogeny were the most startling of those come to by the Commission. These were (1) That the virus of yellow fever is contained in the blood; (2) That the specific agent in producing the disease is destroyed or attenuated by exposure to a temperature of 55° for ten minutes; (3) That, so far as laboratory technique known to us at present can prove yellow fever is not produced by a bacterium.

Perhaps, the most interesting part of Mr. Cantlie's paper is that in which he puts the query "Is yellow fever, as known in the West Indies, the local disease it is at present considered to be." There are—he goes on to say—several ailments affiliated in symptoms, and even in signs, with yellow fever. The most notable of these are Weil's disease; (2) Acute yellow atrophy of the liver; (3) Bilious remittent fever; (4) Bilious typhoid; (5) Hæmoglobinuric fever.

Mr. Cantlie does not claim that any or all of these ailments are yellow fever under different conditions of climate and surroundings, but says that he has long felt that we have, perhaps, looked upon yellow fever too much as a disease totally unaffiliated with diseases which present many clinical symptoms in common, and which, under the titles of bilious remittent, bilious typhus, bilious typhoid, epidemic jaundice, and even blackwater fever, are attended by a yellowness which is frequently as marked as any that occurs in yellow fever, and yet are not named after that symptom. All diseases of an icterohæmatogenous type, attended by fever, black vomit, etc., Mr. Cantlie and others think may belong to a group of fevers designated yellow, of which, up to now, yellow fever alone has borne the family name.

The Danger of Ill-Ventilated Rooms.

The circumstances attending the death of Zola, pointed a moral which most of the medical journals have been quick to draw attention to. Many excellent and apposite articles have been written inveighing against the habit of the majority of civilized people, of excluding fresh air from their rooms, and especially from their sleeping apartments. If the outside air be in the least cold or damp, windows are kept tightly closed, for fear that colds may be contracted, while the greater danger of breathing a vitiated atmosphere is entirely overlooked.

The London Hospital seized the occasion of Zola's sad end to deliver a much-needed lecture to the British people on the evil effects of unventilated houses. After referring to Zola's death by asphyxiation, and stating the fact that consumption is frequently spread by means of contaminated air in living and sleeping apartments, the article goes on to say: "The English are always boasting that they are a cleanly people, and undoubtedly an upper-class Englishman does spend an inordinate amount of time in cleansing himself. As *Punch* has it, 'e's orful proud of 'is flesh, 'e is.' But the average Englishman with his woolen shirts, which are only washed in tepid water, his cloth clothes which are never washed at all, his carpets which retain the dust of years, his stuffy woolen colored furniture which lasts for generations, and his beds which are hardly ever unpicked or stoved, is by no means the cleanly animal he thinks himself. Still, even these things would not be so bad if John Bull would but ensure a free current of air all through his living rooms. But that is just what Mrs. John Bull will by no means allow. Fresh air is 'smutty' and night air is 'unhealthy.' So the windows must be shut. What sort of night air could be more 'unhealthy' than the fogs which cover the river Thames, and what air could be harsher than that of Hampstead in mid-winter? Yet all winter through there are sick people lying out on the verandas at St. Thomas' Hospital and at the Mount Vernon Consumption Hospital, being brought round again to life by this 'unhealthy' air after being nearly killed—by inches, it is true—by the very thing that killed M. Zola at once, namely, the lack of open windows."

In many ways the inhabitants of the cities of the United States are greater sinners in their disregard for the health-giving properties of fresh air than their British cousins. Office buildings, public buildings, and frequently private houses, are heated to an absurdly high degree. In the winter time, too, windows are kept religiously shut, and ventilation is generally ineffective. The consequence is that an individual who has been breathing this hot, dry air for several hours, is extremely susceptible to cold, and when he goes out into the fresh, brisk air of a winter's day, he promptly contracts a cold. This fact accounts for the great prevalence of catarrh in this country, as well as for the mortality from pneumonia and other complaints of the respiratory organs. Many diseases may be avoided by living in well-ventilated rooms, and breathing all the fresh air possible.

Should Fever Be Treated?

Merck's Archives for October has an editorial with the above title. After stating the well-known fact that physicians practising among the poor and ignorant are compelled to give drugs in fever cases whether they deem it the most advisable course or not, the writer proceeds to discuss the question as to whether fever should ever be treated, seeing that it is a symptom and not a disease *per se*. The old medical aphorism reads "Treat the cause and not the symptom." This, although it sounds plausible and well, is frequently utterly worthless in practice. It is valueless in practical application for two reasons: (1) because we cannot always reach the original cause of the disease, or, if we can, it is beyond our control; and (2)—and this is an important point—a symptom of disease may in itself, unless relieved, prove dangerous to life, or, if not directly dangerous, it may cause other symptoms which may themselves prove highly detrimental or even fatal.

The foregoing view of the matter is an obviously reasonable one. Fever in itself, if not checked, will produce dangerous, even fatal changes. Authorities—among them Liebermeister—claim that it produces not only muscular mischief, but also degeneration of brain and nerve tissue, and this degeneration is, in its turn, the cause of the delirium and other disturbances of the central nervous system.

The article in *Merck's Archives* concludes with the following statements: (1) Fever, of elevation of temperature, is a symptom of disease, and not a disease *per se;* (2) Though but a symptom, it may, after reaching a certain degree, produce, in its turn, great functional disturbances, or even organic changes, and thus prove directly or indirectly the cause of death or of great permanent physical or mental injury; (3) When the pyrexia is of a mild character—say between 100° and 102° F.—it should generally be let alone; (4) A temperature between 103° and 105° F. should generally, and a temperature above 105° F. should always, be treated—treated watchfully, carefully, but energetically; (5) Antipyresis may not only obviate the bad results due directly to the fever, but it may have a good effect on the course of the original disease. As to how fever should be treated—whether by hydrotherapy, coal-tar antipyretics, refrigerants, or cardiac depressants—that, as Rudyard Kipling says, is another story.

News of the Week

Scarlet Fever Serum.—In the bulletin of the Health Department of Chicago for the week ending October 25, Commissioner Reynolds says, regarding Class's scarlatina germ, described in the MEDICAL RECORD of September 2 and October 7, 1899: "The organism of this disease is now identified by the laboratory experts as readily and as certainly as is the diphtheria organism, and it is a cause of chagrin to the department that its limited resources prevented the discoverer of the germ from following up his efforts to prepare a curative serum for the disease similar to that of antitoxin for diphtheria. A photograph in the Commissioners' office shows the discoverer, Dr. W. J. Class, one of the department medical inspectors, demonstrating the scarlet-fever organism before a group of bacteriologists and physicians in the laboratory department, April 10, 1899. Cultures of the organism were subsequently taken abroad by Dr. Gradwold of St. Louis, and there can be no doubt that the scarlet-fever serum prepared by Professor Moser of the St. Ann's Hospital for Children in Vienna, and exhibited last month at the Congress of German Physicians and Naturalists at Carlsbad, is the product of these cultures. Professor Moser reported that he had used the serum on 400 scarlet-fever patients in his hospital with a mortality of between 8 and 9 per cent., while the mortality in the other hospitals where the serum was not used was double that percentage. The Austrian Government promises to vote a sum of money sufficient for the perfection of the serum and its production in large enough quantity to furnish all the children's hospitals in Vienna." When the Chicago Memorial Institute for Infectious Diseases is established some practical results are looked for, for the chief object of the foundation of this institution was the study of scarlet fever and the production of a serum for its cure.

A Disclaimer by Dr. Wyeth.—Dr. John A. Wyeth of this city writes: "A report has been widely disseminated through the secular press that I made a statement to some newspaper reporters that Professor William H. Welch had claimed the discovery of a universal virus or remedy which would immunize the human race from all forms of infection. No such claim was made by Professor Welch, nor has such statement been authorized by me."

Wholesale Inoculation against the Plague in India. A despatch to *The Sun* from Calcutta says that the Government of the Punjab recently took what it considered was an extreme step to prevent the spread of bubonic plague in that province. It issued an order directing that the entire population should submit to inoculation against the disease at the hands of the sanitary officers, but at the same time it was feared that the natives, with their usual antipathy to sanitary precautions, would bitterly oppose compliance with the order. Much to the surprise of the authorities, however, no opposition is being offered, and the work of inoculation, which is a tremendous task, is progressing satisfactorily. As instancing the willingness of the inhabitants to undergo the operation, several native regiments have presented themselves in bodies for the treatment.

Cholera in the East.—Reports recently received by the Public Health and Marine-Hospital Service show that cholera has been making fearful ravages in the Philippines and the adjacent coast of Asia. It is estimated that 75,000 cases with nearly 60,000 deaths have occurred in the Philippines since the beginning of the epidemic at the end of March. In some of the towns 10 per cent. of the native population have died. Although some of the provinces are still suffering severely, the epidemic is gradually subsiding. A cable report from Gov. Taft, received October 30, says that the cholera has practically disappeared from the Island of Luzon, and that in Manila there have been an average of only two cases a day during the last ten days. In all, twenty provinces are now practically free from the cholera. Only five provinces are now seriously affected the provinces of Iloilo, Occidental Negros, Capiz, Samar, and Misamis. The mortality, which in the beginning reached 90 per cent., has been greatly reduced, and is now generally below 50 per cent. Cebu has already been declared a clean port, and Manila will be so declared on November 1.

In Japan the latest advices show that there have been 4,329 cases and 1,650 deaths from cholera.

In China the Provinces of Hunan and Shansi are most affected. The disease is epidemic at Nanking, which reports 40,000 deaths, at Shoo-Yanghsien, with 3,000 cases a day, and a number of other cities. In Hongkong, since the beginning of the outbreak, there have been 459 cases and 396 deaths, but the local authorities declare the colony free from plague infection. Surgeon-General O'Reilly has received a report from Lieut. W. J. L. Lyster of the medical department, who is attached to the United States Legation Guard at Peking, from which it appears that the American soldiers are the only foreigners who have escaped the epidemic of cholera up to date.

Gift of a New Lectureship to the Johns Hopkins.—Dr. and Mrs. Christian A. Herter of this city have presented to the Johns Hopkins University the sum of $25,000 for the foundation of a memorial lectureship in the medical department "designed to promote a more intimate knowledge of the researches of foreign investigators in the realm of medical science." The end is to be secured by inviting each year some European physiologist or pathologist to deliver one or more lectures at the Johns Hopkins University upon a subject with which he has been identified. The lecturer will receive as an honorarium the annual income of the endowment.

The Chicago Pasteur Institute.—In the two years and a quarter since the opening of this institute 1,538 persons were treated for threatened rabies by the Pasteur method. One thousand three hundred and eighty-two persons were bitten by dogs, 48 by cats, 55 by horses, 15 by skunks, 5 by wolves, 11 by cows, 5 by calves, 1 by a burro, 2 by coyotes, 1 by a rat, 3 by mules, 1 by a pig, and 9 by hydrophobic human beings. Seven hundred and sixty-two persons received severe and multiple lacerated bites on the hands and wrists, 209 on the head and face, 208 on the arms, 327 on the legs and thighs and 32 on the trunk. Following the rule of Pasteur, the patients treated were classified as follows: (1) Persons bitten by animals recognized and ascertained to be rabid by the test experiment made in the laboratory or by the death of other persons or animals bitten by the same animal; of this class 660 were treated. (2) Persons bitten by animals recognized to be rabid by the symptoms of disease shown during life; of this class 647 were treated. (3) Persons bitten by animals strongly suspected to be rabid; of this class 231 were treated. Seven deaths were reported, giving a mortality of 0.45 per cent.

An X-Ray Suit Dismissed.—A young woman recently brought suit in the Supreme Court of this State against two dentists, asking $50,000 damages for *x*-ray burns. She was suffering from some disease of the jaw and was advised to submit to an *x*-ray examination. This she did, with the result that her face and shoulder were burned so severely that permanent disfigurement resulted and the hair on one side of the head has fallen out. In her complaint she said that "one million volts of electricity" had been turned upon her. The examination, from which the injury was alleged to have resulted was not made by the defendants, but was only advised by them, and the complaint was dismissed.

Tri-State Medical Association of Mississippi, Arkansas, and Tennessee.—The Nineteenth annual meeting of this association will be held at Memphis, Tenn., November 11, 12, and 13, 1902, under the presidency of Dr. J. B. McElroy.

The Egyptian Medical Congress.—The President of the Egyptian Medical Congress, which is to be held at Cairo on December 19 to 23, is Dr. Ibrahim Pacha Hassan; the Secretary-General Dr. Voronoff. The principal object of the congress is the study and discussion of diseases occurring in warm climates. There will be four sections: Pathology, President, Dr. Comanos Pacha; Diseases of Hot Climates, President, Dr. Ruffer; Surgery, President, Dr. Milton; Ophthalmology, President, Dr. Mohamed Bey Eloui. A combined meeting of all the sections will be held for the discussion of hepatitis and abscess of the liver, and the Sections of Diseases of Hot Climates and of Surgery will meet together to discuss bilharzia hæmatobia. Cholera, dysentery, leprosy, and plague are among the subjects to be discussed by the Section of Pathology; while Egyptian ophthalmia is one of the subjects selected for the consideration of the Section of Ophthalmology; the Section of Diseases of Hot Climates will discuss, among other subjects, malaria and filariasis. The official languages of the congress will be French and Arabic, but German, English, Greek, and Italian may also be employed. Special reductions in fares will be granted by certain steamboats and railway routes to Cairo, and upon the Nile steamboat, as already announced; the hotels in Cairo also offer special terms. Members reaching Cairo before the congress begins will find arrangements made for them to visit various places of interest in Cairo on December 17 and 18. On December 25, after the congress, there will be an excursion to Sakkarah; on December 26 to 30 there will be a short excursion to Upper Egypt by railway; and on December 31 and January 1, 1903, an excursion on the Suez Canal. The Khedive, the Egyptian Government, and the Committee of Organization will give fêtes and receptions in honor of the congress.—*British Medical Journal.*

Prescribing Druggists in Trouble.—A Supreme Court jury a few days ago gave a lawyer of this city a verdict for over $3,000 damages against a firm of druggists for having sold him a medicine that made him sick. The plaintiff said that he had asked for some quinine to cure a cold in the head, but the clerk recommended "something much better." The first dose he took made him very ill, and he was under medical care for two weeks. He asked for $5,000 damages, but got $3,281.08.

In Memory of Virchow.—On October 20 the Berliner Verein für Innere Medicin held a special meeting in memory of the late Professors Gerhardt and Virchow, Professor v. Leyden delivering the oration. On the 29th of the same month, a Virchow memorial meeting of the Berliner medicinische Gesellschaft was held. It is proposed to erect a statue of Professor Virchow in Berlin, and a meeting to organize a committee to raise funds for this purpose was held at the instance of Professor Waldeyer on October 15.

Testing Food Adulterations.—The testimony regarding the effects upon the human system of continued small doses of boric acid and other food preservatives, as well as of coloring matters and adulterants in general, is so conflicting that the Agricultural Department in Washington is about to submit the question to a test *in corpore vilo.* A number of healthy, but impecunious individuals have been secured who are willing to subject themselves to experiment in exchange for free board, and they will accordingly be fed for stated periods on food with various preservatives and adulterants added, and the effect of these substances upon digestion, body weight, and metabolism will be scientifically determined. When the experiments have been concluded and the results announced, some one else will probably repeat them and reach diametrically opposite conclusions. In the mean time a good many men will have "victualed free" for a time without suffering any special injury.

Results of the Mosquito War in South Orange. The Committee of the South Orange (N. J.) Village Improvement Society which has been endeavoring for two seasons to exterminate the mosquitos of the vicinage, recently made a report on the work accomplished. Mr. Spencer Miller, Chairman of the Committee, said: "Speaking roughly of our results, we should say that in 1901, by the use of oil alone, we reduced the mosquitos at least 50 per cent. This year by adding drainage to the oil work we have surely cut down the supply 75 per cent. We can hope another year to reduce the supply 10 per cent. more, but that is the best we can do until the surrounding communities take up the fight. The area we have been treating is two miles long and one and three-quarters wide. This year we expended $1,100, and our results are much more emphatic than last year. Ten thousand dollars spent at once would drain and fill every wet spot in town, and the problem would take care of itself." Mr. Miller said that a convention would be held in New York soon, which committees and health officials from points within 100 miles of New York would attend and discuss means for a concerted campaign against the pest.

Washington Medical Society.—At the annual meeting of this society, held recently, the following officers were elected for the ensuing year: *President,* Dr. Charles McCutcheon, Tacoma; *First Vice-President,* Dr. Geo. W. Libbey, Spokane; *Second Vice-President,* Dr. A. E. Stuht, Colfax.; *Secretary,* Dr. A. H. Coe, Spokane; *Treasurer,* Dr. J. B. Eagleson, Seattle.

Prizes for Essays on Preventive Medicine.—The two prizes offered in January of this year by the Maltine Company for the best two essays on "Preventive Medicine" were awarded on October 18 by the judges, Drs. Daniel Lewis of New York, Charles A. L. Reed of Cincinnati, and John Erwin Rhodes of Chicago. The first prize of one thousand dollars was awarded to Dr. W. Wayne Babcock of Philadelphia for an essay entitled "The General Principles of Preventive Medicine," and the second prize of five hundred dollars to Dr. Lewis S. Somers also of Philadelphia for an essay on "The Medical Inspection of Schools: a Problem in Preventive Medicine." Although two hundred and nine essays were submitted by contestants from nearly every State in the Union, from Alaska, and from the Dominion of Canada, the two successful competitors are from the same city and live on the same street within less than a quarter of a mile of each other.

Pennsylvania State Medical Examinations.—At the examinations for license to practise medicine in the State of Pennsylvania, held in June last, there appeared eighty-nine graduates of the University of Pennsylvania, of whom eighty-seven passed, with a general average of 84.54; nineteen graduates of the

Woman's Medical College, all of whom passed, with a general average of 82.91; eighty-six graduates of Jefferson Medical College, of whom eighty-three passed with a general average of 82.47; seventy-six graduates of the Medico-Chirurgical College, of whom sixty-eight passed, with a general average of 80.45; and fifty-nine graduates of the Western University of Pennsylvania, of whom forty-nine passed, with a general average of 79.31.

Measles Epidemic in Kamchatka and Alaska.—The natives of the Kamchatka Peninsula are reported to be suffering terribly from measles, over ten thousand having already died since the beginning of the epidemic. The same disease is ravaging the Arctic coast of Alaska and Herschel Island, the mortality there being excessive.

The Finsen Light for Lupus; a Correction.—In the report of Dr. Kinnicutt's paper on the Finsen light, read before the New York State Medical Association, the speaker was made to say (page 714) that "tuberculosis was a dermatosis which was especially favorable for a study of this subject." The report should have read "lupus vulgaris" instead of "tuberculosis."

The New York Obstetrical Society.—At the annual meeting of this society, held October 14, 1902, the following officers were elected: *President*, Dr. Egbert H. Grandin; *First Vice-President*, Dr. J. Clifton Edgar; *Second Vice-President*, Dr. G. W. Jarman; *Recording Secretary*, Dr. W. S. Stone; *Assistant Recording Secretary*, Dr. H. C. Taylor; *Corresponding Secretary*, Dr. E. E. Tull; *Treasurer*, Dr. J. Lee Morrill; *Pathologist*, Dr. W. S. Stone.

Philadelphia County Medical Society, South Branch.—At a stated meeting held October 24, Dr. W. M. L. Coplin spoke upon "The Morphology of the Blood," illustrating his subjects with lantern demonstrations; Dr. L. Napoleon Boston discussed "Blood Examination by the Microscope;" Dr. Randall C. Rosenberger read a paper on "Bacteriology of the Blood;" and Dr. F. J. Kalteyer one on the "Parasitology of the Blood."

Philadelphia Neurological Society.—At a stated meeting held October 28, Dr. F. X. Dercum referred briefly to "A Case of Astasia-abasia" in a colored boy in which recovery followed rest in bed with suggestion but without hypnosis. Dr. Dercum also presented "A Case of Unusual Dystrophy of the Right Hand." The patient was a large woman about thirty years old, who had recently gained 100 pounds in weight and who presented a painless tumefaction of the soft tissues of the hand, wrist and lower portion of the forearm, with increased color of the overlying skin. This condition had been present for several years, following a somewhat acute swelling of all four extremities. The Secretary read for Dr. Theodore Diller of Pittsburg a communication entitled "A Case of Myasthenia Gravis Complicated by Angioneurotic Edœma." Characteristic symptoms were present and these. together with the œdema, were thought to be of toxic origin. Dr. Chas. K. Mills exhibited "A Case with Symptoms of Myasthenia Gravis (?) Resulting from an Electric Shock of 1,300 Volts." The patient was a man who presented weakness and wasting of bulbar and other muscles following the accidental passage through his body of the high voltage mentioned, with preservation of the knee-jerks and the ankle-jerks and of the functions of the sphincters. The possibility of the case being one of muscular atrophy of bulbospinal origin was suggested. Drs. Samuel W. Morton and Chas. K. Mills reported "A Case of Acute Bulbo-spinal Paralysis." The patient was a man who, in the pursuit of his profession as an electrician, was compelled to submit many times daily to the passage through his body of the current from a battery of four dry cells. Dr. Theodore H. Weisenberg read by invitation a communication entitled "The Pathological Changes Induced by Electric Currents of High Potential." Dr. William G Spiller presented "A Case of Bulbar Paralysis in its Earliest Stages." The possibility of the case being of other origin was admitted, and the difficulty of diagnosis at this stage pointed out. Dr. Alfred Gordon read a paper entitled "A Study of Sensation in Motor Paralysis of Cerebral Origin, based upon Thirty-five Cases." In a large proportion of the cases alterations in one or another variety of sensation were present, but the significance of the changes was not clear. Dr. Francis X. Dercum reported "A Case of Adiposis Dolorosa with Involvement of the Joints."

Philadelphia County Medical Society.—At a stated meeting, held October 22 ,Dr. Albert P. Francine read a paper entitled "The Etiology of Gastroptosis." The causes of this condition are of two kinds, namely, predisposing and exciting. The former comprise inherited tendencies and constitutional weakness, the latter mechanical influences, such as constriction of the waist by clothing, pyloric obstruction, and other causes of distention of the stomach. The displacement of the stomach may occur independently or be associated with displacement of other abdominal viscera. Dr. J. Dutton Steele presented a communication entitled "Preliminary Report upon Some Experiments to Determine the Pressure in the Bile-ducts in Floating Liver." These observations go to show that displacement of the liver may give rise to such changes in the relations of the biliary ducts as to interfere more or less seriously with the flow of bile into the duodenum. Dr. Alfred Stengel pointed out that the co-called Dietl's crises might in some instances be induced by displacement of the stomach, particularly its pyloric extremity, through descent of the right kidney or of the liver. Dr. Henry D. Beyea discussed the surgical treatment of gastroptosis. Among the operations that have been advised to this end are shortening of the gastrohepatic and gastrophrenic ligaments, alone or in conjunction with the formation by suture of a fold in the greater curvature of the stomach, and attachment of the stomach to the anterior wall of the abdomen. The latter procedure is to be condemned as interfering with the mobility of the organ and thus constituting a source of danger. Dr. Beyea has devised an operation of the former type, as have also others, and the results have been entirely satisfactory. Operation should, of course, be undertaken only after all other measures have failed to bring relief. Dr. Andrew J. Downes read a paper entitled "Electrothermic Hemostasis in Hysterectomy for Cancer." He spoke of the safety and the security attending this mode of operation, as well as the rapidity with which it can be executed; and he demonstrated a series of instruments that he has devised for the purpose. These consist of forceps-like clamps, one blade of which is grooved to receive a projection or shoulder from the opposite blade, and both of which are lined with platinum, which is rendered incandescent by the passage of an electric current. Several cases were related in which the method has been employed with the utmost satisfaction. The result of the application is cooking of the tissues, so that infection and hemorrhage are prevented, without the necessity for a single ligature. Drs. Barton Cooke Hirst, Chas. P. Noble and John M. Fisher spoke from personal observation in the highest terms of the usefulness of the mode of operation and of the excellence of the instruments and their successful application. Dr Herman A. Bray read a paper entitled "Diseases of the Rectum as a Specialty" He dwelt upon the importance of diseases of the rectum, of the neglect that has been bestowed upon them, and of the discomfort to which they are capable of giving rise. Dr. Gwillym G Davis exhibited a modification of the Kelly rectal speculum. In this instrument the edges are less sharp than in the original, and the plunger is acorn-shaped instead of being cylindro-spherical.

Pathological Society of Philadelphia.—At a stated meeting, held October 24. Dr. W. M. L. Coplin presented a communication entitled "Myosclerosis with Especial Reference to Elastic Myocardial Sclerosis." He described a form of inflammation or degeneration of the myocardium in which elastic instead of ordinary fibrous tissue replaces the muscular structure of the heart, and he exhibited a heart presenting occlusion of a coronary artery with anæmic necrosis and fibroid substitution, together with the presence of elastic tissue in the heart-muscle at various points. During life there had been attacks of angina pectoris, in one of which death took place. It was thought that the attacks were due to repeated embolism of the coronary artery. Drs. D. L. Edsall and C. A. Fife presented a communication entitled "A Case of Pyloric Carcinoma with Symptoms Simulating Gastrocolic Fistula." About two years before death there had been symptoms suggestive of malignant disease of the stomach, but no tumor was detected, and recovery apparently followed. At a later date there was vomiting of feculent matter, and introduction of air into the large intestine rectum was followed by dilatation of the sigmoid flexure and the descending colon, abruptly subsiding in the left hypochondrium. After the introduction of milk into the rectum, the vomited matters contained a fine emulsion of fat, which could have been derived from no other known source than the enema. Other evidence was obtained indicating that materials introduced into the rectum were subsequently ejected from the stomach. It was, accordingly, believed that a communication existed between the colon and the stomach. Post-mortem examination, however, disclosed the existence of extensive carcinoma at the pyloric extremity of the stomach, reducing the pyloric orifice to a small opening. Drs. Chas. K. Mills and William G. Spiller reported a case of external spinal pachymeningitis implicating the entire ventral surface of the spinal dura." The patient complained of inability to walk, with a certain amount of rigidity and contractures and exaggeration of the reflexes generally. Post-mortem examination disclosed a most extensive and intense condition of inflammation of the anterior aspect of the external surface of the spinal dura mater throughout its entire length, the membrane being attached to the bodies of the vertebræ, and in places compressing nerve-roots and cord itself, and giving rise to areas of degeneration in the posterior and the lateral columns, and in places in the entire circumferential periphery of the cord. The dorsal portion of the cord was extremely small.

Obituary Notes.—Dr. W. W. Archer of Clifton Springs, N. Y., died on September 26 of organic heart disease, at the age of fifty-six years. He was a graduate of Hobart College, Geneva, in the class of 1867.

Assistant Surgeon Walter E. Griffin of the Navy died on October 28, at the Cavité naval station, Philippine Islands. He had been in the service only eight months, having been appointed from Michigan on February 20. Dr. Griffin went to the Philippines in April.

Dr. Andrew [illegible] died on October 25, 1902, of apoplexy. He was graduated from the Medical College of Ohio in 1861 and began practice in Chicago in 1863. He was chief surgeon to Alexian Brothers' Hospital of Chicago for the first twenty-four years of its existence. He was surgeon to Cook County Hospital for fourteen years and to Michael Reese Hospital for seven years.

Dr. Joseph H. Sheppard died at Bridgeton, N. J., on October 23, at the age of seventy four years. He was graduated from the medical department of the University of Pennsylvania in 1849, and was at one time a resident physician in the Philadelphia Hospital. During the Civil Was he served as a surgeon in the United States Army, and at the time of his death he was a member of the Pension Examining Board.

Dr. Daniel E. Hughes, for twelve years chief resident physician to the Philadelphia Hospital, died of peritoneal tuberculosis on October 28, at the age of forty-five years. He was graduated from Jefferson Medical College in the year 1878, and was the author of "A Compend of the Practice of Medicine."

Obituary.

FREDERICK A. PACKARD, M.D.,

PHILADELPHIA, PA.

Dr. Frederick A. Packard died in Philadelphia on November 1, at the age of forty years, from exhaustion in the sequence of typhoid fever complicated by appendicitis, intestinal perforation, and phlebitis. He received his preparatory education at Rugby Academy, and his academic education in the University of Pennsylvania, from the medical department of which latter institution he was graduated in 1885. After serving as resident physician in the University and Pennsylvania Hospitals, he became successively visiting physician to the Philadelphia, Episcopal, Methodist, and Children's Hospitals, and hardly more than a year ago physician to the Pennsylvania Hospital.

A little more than a year ago he was elected one of the trustees of the University of Pennsylvania. In the the absence of Dr. Horatio C. Wood, he delivered the lectures on therapeutics in the medical department of the University during the session of 1901-'02. Dr. Packard was a member of the Association of American Physicians, of the American Pediatric Society, of the American Medical Association, of the College of Physicians of Philadelphia, of the Philadelphia County Medical Society, of the Pathological Society of Philadelphia, of the Philadelphia Pediatric Society, and of the Philadelphia Neurological Society. He had been President of the Pathological Society of Philadelphia and of the Philadelphia Pediatric Society. He was a generous contributor to medical literature.

He is survived by a widow, by his father, Dr John H. Packard, who was a medical director in the United States Army during the Civil War, and for many years one of the surgeons to the Episcopal and the Pennsylvania Hospital, by a brother, Dr. Francis R. Packard, editor of the *American Journal of the Medical Sciences* and professor of otology in the Philadelphia Polyclinic, and by another brother, Mr. Chas. S. W. Packard, president of the Pennsylvania Company for Insurances on Lives and Granting Annuities. Dr. Packard was one of the most industrious, most progressive, and most brilliant clinicians of his generation, and his fine qualities combined with his high professional attainments, served to gain for him the esteem and friendship of and to endear him to all brought in contact with him. In his death the medical profession of Philadelphia and of the United States loses a most distinguished and worthy representative.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PROFESSOR ERB'S ADDRESS—SIR F. TREVES AT LIVERPOOL—SOCIETIES OPENING SESSION—SOCIETY OF MEDICAL OFFICERS OF HEALTH—OWEN TESTIMONIAL—NEW STAFF COLLEGE—THE LATE MR. BIRD.

LONDON, October 17, 1902.

PROFESSOR EBR of Heidelberg has been over here, and was entertained at a dinner on Saturday. He came on the invitation of the West London Postgraduate College, and opened their session with a lecture in which he described some of the most recent advances in neurology, and especially two diseases which he has himself differentiated. At the dinner, Dr. Hood, the chairman, spoke of the lecture as one that would ever remain a classic on the subject, and expressed the gratitude the college and staff of the hospital owed to the illustrious professor for coming to address them. In replying to the toast, Professor Erb said that if he were not so proud of being a German, he would like to be an Englishman, especially at that moment, as he would have a better command of the language to express his gratitude for his reception. He congratulated the college on its work, such as that being carried on also in Germany, and which tended to develop and strengthen medical science, which has no international or frontier disputes. He held that England and Germany had done more than all the rest of the world to advance natural and medical science, and he hoped the two great branches of the Teutonic stock would continue to work together in the future, as they had done in the past, for the good of suffering humanity.

Of the lecture itself, it would be impossible to give an adequate description in the space at my disposal, but I may say that it deserves the attention of every neurologist—which, indeed, it is certain to receive—and even your general readers may study it with advantage, for it is sure to be republished on your side. The *Lancet* has already printed it here. He described rather fully two forms of chronic myelitis, for the clear differentiation of which we are indebted to him. His "spastic spinal paralysis—primary spastic paraplegia"—which he described in 1875, remained for many years a matter of doubt, on account of the difficulty of obtaining sufficient anatomical proofs to satisfy all, but eventually this was obtained. The rarity of the disease and its extreme chronicity accounts for the duration of a certain degree of scepticism, and moreover it does not of itself lead to a fatal termination. The second form of disease discussed was differentiated by Professor Erb in 1892. It occurs almost exclusively in patients who have had syphilis, and he named it "syphilitic spinal paralysis." It is distinguished from the simple form by the presence of disturbances of sensation and bladder function; from transverse myelitis by the absence of marked paralytic phenomena with decubitus cystitis; from meningomyelitis by the absence of meningitic and root symptoms with their variable intensity and complicating paraplegia. Actual syphilitic myelitis, spinal gummata, softenings and hemorrhages due to syphilitic disease of the vessels, generally present clinical pictures of a different kind, though they may be difficult to recognize individually. Other spinal diseases do not cause much difficulty in diagnosis. As to prognosis, recovery can only be hoped for in the earlier stages, but improvement often occurs, and the power of gaining a livelihood may be obtained for a considerable period. Treatment with mercury and iodides must be continued—often for years. The professor pointed out that the effects of syphilitis on the cord are manifold and erratic, and as we are learning that tabes is due to syphilis, so other alterations in structure—so far considered non-specific—may have the same origin.

The *Religio Medici* of Sir Thomas Browne has held such a high place for some 260 years that few men would like to suggest a comparison between that classic and anything of their own. Yet this is what Sir F. Treves deliberately did in his address to the Liverpool students, last Friday. He told them there was much in the *religio medici* personal to the author, which would be unacceptable to the modern physician, and a not inconsiderable part which rests upon unchangeable foundations and is beyond criticism. To Sir T. Browne, he said, disease was the outcome of an influence outside the body, had nothing natural in its processes, and nothing beneficent in its manifestations; every symptom was regarded as noxious, and to be stamped out with unconsidered violence. But the modern *religio medici* looked on the human body as highly organized, frail, finite, and necessarily prone to dissolution. It grows, reaches its maximum capacity, and declines. In the progressive enfeeblement of age there is nothing unnatural, and disease is the outcome of natural processes, and many of its manifestations are marked by a beneficent purpose, having for its end the cure and not the destruction of the patient. As examples, tuberculosis and appendicitis were cited to show that inflammation is always a benevolent process, the purpose of which is to cure. Turning to the second element of the *religio medici*, the relation of the physician to his patient, Sir Frederick said the student could keep no better motto before him than this: *Fortiter, fideliter, feliciter.* We need to be strong, not with crude force, but with the power of fine cultivated sense, quick perception, and ready judgment; faithful in right doing, and with truest care for the patient's interest; kind, with the genuine sympathy which cannot be assumed or mimicked.

Later in the day Sir F. Treves opened the new operating theater of the Royal Infirmary, which is the gift of Mr. Ralph Brocklebank. In doing so, he said that twenty or thirty years ago the operating theater was often a neglected part of even a great hospital. It has, since the antiseptic system was introduced, become the most conspicuous, and in some sense the most important. He could pay this theater no higher compliment than to say it was worthy of the reputation of the surgeons of Liverpool, who had not gone in for anything fantastic, but whose work was characterized by sturdy common sense.

Not only the schools but the societies have now begun their winter sessions. On Monday the Medical Society of London opened with an inaugural address by the new president, Mr. Pearce Gould. He alluded to the death of Professor Virchow, who was an honorary Fellow of the Society, and the great influence he had exercised upon two generations of pathological observers. The wide extent of Virchow's interests was also mentioned, and a doubt expressed as to whether the medical profession was wise to avoid politics or not. Mr. Gould also dwelt upon the value of this and similar societies, and the great advantage of attending their meetings over merely reading reports.

The President of the Clinical Society, Mr. Howard Marsh, in his address, reminded his audience that the society was established to promote clinical science by accurately observing, recording and discussing cases and their treatment. Progress was slow, not because medicine is an inexact science, as is so often said. It was founded on biology, which he spoke of as exact, and said it may itself become exact. But the bases, unlike those of astronomy, themselves vary. Yet research will meet with success. Though the society chiefly has to study individual cases, he thought certain questions might, from time to time, be submitted to small committees for reports which could be carefully debated.

Afterward a paper was read which excited considerable surprise, in which it was claimed that asthma was more amenable to local nasal treatment when the nasal passage was normal than when it was obviously diseased. Rhinologists will scarcely go further than that.

The annual meeting of the Society of Medical Officers of Health was held last Friday, when Dr. Spottiswoode Browne, president, delivered a rather cheering address. He looked hopefully at the progress of electricity as a motor force likely to lead to the erection of small factories in rural districts. He held that there should be a medical man attached to every school, who should attend within an hour of the morning assembly, and should have authority to examine every child about whose state the teacher was suspicious.

The annual dinner of St. Mary's Hospital students was attended by some 220, and was made the occasion of presenting to Mr. Edmund Owen, who retires from the active to the consulting staff, with a testimonial of antique plate, an album with an address signed by above 400 pupils and colleagues, and jewelry for Mrs. Owen and daughters. Sir W. Broadbent, in presenting it, said all were sorry to lose his services. Mr. Owen said he was bankrupt in words, and could only repeat "I thank you." He did not claim to have done his duty, but he had tried to do it; in one little respect he claimed he had really done it—in punctuality, not much, and yet a good deal.

The Medical Staff College has held an inaugural dinner in its temporary quarters, where the War Minister made an encouraging speech, in which he said he hoped to see the college accommodated in suitable buildings in London, and he considered the success of the college was assured by the fact that Colonel James was at the head of it.

There was felt a sense of regret at the West London celebration mentioned above on account of the death of Mr. Wm. Bird, consulting surgeon to the hospital, and for many years its Chairman. To him is largely due the greatly improved position of the hospital and its enlarged buildings. He was also a J. P. and chairman of the local bench of magistrates, to the duties of which he gave constant attention. He died on the 4th inst.

LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

THE VAGARIES OF QUARANTINE—SYPHILIS IN ASIA MINOR—SANITARY COMPLACENCY—HÔPITAL DE LA PAIX—TYPHOID FEVER—PUBLIC ADVICE TO PREGNANT WOMEN—MEDICAL SCHOOLS AT BEYROUT—THE AMERICAN HOSPITAL.

CONSTANTINOPLE, October 15, 1902.

BEYOND the monotony of taking off and putting on of quarantine, for and against plague, there has been little of interest in the medical world.

Freedom from quarantine restrictions was declared late in June, but was of short duration, for within a few days after the announcement four cases of plague were reported, two demonstrated, two suspected in Galata and Stamboul—the last case on June 2[illegible]. A circular telegram was issued from the sanitary office by decision of the Superior Council of Health, viz., "Patents of Health delivered to the Shipping at Constantinople and Kavak will even from July 2, bear the following annotation: 'It has been demonstrated that in the city four cases of plague have occurred, one mortal. The three cases have been isolated; the last case of date June 3[illegible].'" The fatal case alluded to in the circular occurred in the person of a child of eight years, living in Galata. The doctors thought at first it was a case of typhoid fever, but later on they determined that it was plague. As usual, Greece, Russia, Roumania, and even Malta, imposed their reglementary quarantine against Turkey, and Turkey against herself, as persons leaving Constantinople for other ports of the Ottoman Empire were subjected to medical inspection and disinfection.

The outbreak of cholera in Egypt was reported on July 21, and this called out all the forces of quarantine. That the former fear of plague has nearly died out in Turkey and the Levant may be shown by the little notice the inhabitants take of the sanitary notifications. Certainly the present plague record of mortality has been so mild that many are sceptical as to the real nature of the disease, though the cases are reported as having been demonstrated by bacteriological examinations. The oddities of quarantine are at times more amusing than alarming. Why, for, instance should Greece impose only forty-eight hours, when Roumania imposes eight days, Bulgaria ten days, and Russia ten or eleven days? And the various sanitary departments, day by day, reduce and increase the periods of quarantine with little or no apparent cause. The dread of cholera, however, remains as of old, and the most severe regulations of quarantine are accepted as safeguards against it.

It would appear that the Health Board and the Palace are not quite in accord with reference to the period of quarantine against Egypt, especially in what concerns Asia-Minor. The Board imposed ten days against passengers, etc., going from Egypt to Syria. The Palace ordered fifteen. The Board resents the action of the Palace, taking its stand on the regulations of the Venice conference, which limits quarantine to ten days. It is stated, however, that Turkey is not bound by this conference, not having subscribed to the regulations.

Syphilis in Asia Minor, to which allusion has been made, appears to be no false alarm. The subject is freely discussed in the Turkish journals. It is stated that the disease prevails in the districts of Braussa, Bassora, Erzeraum, Monastir, and Treluzoud, and that its ravages are extending actively toward other localities not yet contaminated. "Syphilis," states one journal, "in spite of prophylactic measures taken for thirty years, continues its devastations with such activity as forces us to attribute the increasing extension to the ignorance of the population of the rudimentary principles of hygiene. All the measures taken have been unsuccessful. The Imperial Government has spared nothing for the support of hospitals for syphilitics. The annual contribution for this purpose has exceeded 25,000 lire, yet with little success."

It may, therefore, be assumed that the measures taken have not been in accord with the usages and habits of the people, amongst whom the principles of hygiene recommended by authority have little chance of being practised. In connection with this subject a certain Zahidè Ranem (lady) has applied to the competent department to grant her leave to treat syphilitic patients with an infallible remedy which she has discovered. The application is stated to have been granted, and an apartment placed at her service.

Several important changes have taken place in the sanitary service of Turkey. Dr. Cozzonis, the chief of the administration, retired on pension, Dr. Ducas has succeeded to the post. This appointment is hailed with satisfaction. Dr. Ducas has had a good training as Ottoman Delegate on the Egyptian Sanitary Board. Dr. Stiepovitz, late secretary of the Constantinople Board, replaces Dr. Ducas in Egypt.

The twenty-sixth anniversary of His Majesty's accession to the throne has elicited from the medical world a paean of panegyric for the benefit medical science has obtained during his reign. Praise certainly is due, but the following is somewhat highfalutin: "Our hospitable institutions march with the most recent progress of medical sciences, and we possess even hospitals which may compete with no matter what similar institutions abroad. Our sanitary service is so perfected that it has been able to repulse more than one epidemic, which, however, ravaged other places abroad. If sometimes a scourge, as plague or cholera, attempts to penetrate amongst us, it is immediately stifled on the spot, which does not happen in ports the most salubrious of countries, the most advanced in prophylactic hygiene," and so on *ad nauseam* to those who see and smell intelligently.

His Majesty has shown his solicitude for the further improvement of the "Hopital de la Paix" at Chichli, the oldest hospital in Constantinople, by giving it a large amount of land of great value, and enclosing it with a good wall and railings. The French Sisters of Charity thus become proprietors of an establishment of [illegible] class, with still farther room for improvement. A marble slab has been erected to commemorate the event, with the following inscription:

"Le 27m. fevrier, 1902.
S. M. I., Le Sultan Abdul Hamid II,
désireux de donner un nouveaux témoinage
de sa compassion
pour les malades et les déshérités
a accordé, à la demande de
S. Ex. M. Constans,
Ambassadeur de France,
le terrain à l'Hôpital de la Paix,
et a fait construire
à ses frais le mur de
clôture."

The ceremony of transfer was made in presence of H. E. M. Constans, Ambassador of France, and of Madame Constans.

The Imperial Society of Medicine, some few years ago, had an interesting discussion on the mortality of typhoid fever in Constantinople. It has been maintained by many practising physicians that typhoid fever was of a milder form, and less fatal here than in many other places. Dr. Kambouroglou, surgeon-in-chief of the German Hospital, has devoted an able article on this subject, communicated to the society on June 6, 1902, in which he clearly shows, from public and private statistics, that true typhoid fever is just as fatal in Constantinople as elsewhere. The term "typhoid" is somewhat loosely used in Turkey, and covers many of the unclassified forms of gastric and gastroenteric irritations attended with fever, even the so-named Malta fever.

The society, at its meeting of June 13, passed a resolution to address to the public, through the local press, certain advice to prevent accidents and complications that might arise during the course of pregnancy, in labor, or in consequence of labor.

This was done, and a series of ten (10) paragraphs appeared, based, apparently, on the supposition that pregnancy is a disease, and couched in corresponding language. Paragraph 5 may be quoted as an illustration:

"Toutes femmes qui accouchent dans de bonnes conditions, ne doivent jamais avoir le fièvre; la soi-disante: fievre de lait n'existe pas, toute elevation de la temperature doit être attribuée à une infection, et par suite dès qu'un constate la moindre fièvre, il faut appeler aussitôt le medecin pour que celui-ci puisse déterminer l'origine réele de cette infection et agisse en conséquence sans perdre un instant."

It is difficult to understand to what class of the population these instructions are addressed. Doctors abound—alas! The family doctor is an institution. Why, then, a society of medicine should consider it necessary to address the public on such a delicate subject, through the public press, is one of the curiosities of medicine.

To the index expurgatorius of drugs have been added bicarbonate of sodium, cream of tartar, certain medicated cottons, and certain animal extracts, like thyroid.

The American School of Medicine at Beyrout claims to be placed on the same footing as the French school. Presumably it has equal rights. It may, however, be a fair question if either of these establishments are necessary even in Turkey, when outside the Capital. The teaching cannot compare with the provincial schools of Germany, France, or America. The preliminary education is scarcely enough; clinical material is not abundant; facilities for dissection are lacking. The standard of the graduates can be but mediocre, and this is so far evident that those who can afford it take further courses and degrees in America, France, and Germany. The local papers report that in consequence of some deaths after operation in the American Hospital at Van, the government proposes to close it, and build a hospital of their own, as they consider the American one lacks in sanitation!

The old "British Seamen's Hospital" in Galata is in process of demolition. A new one will be constructed on the old site. Public rumor says 20,000 pounds will be spent on it, which is unlikely.

In view of the sanitary, quarantine, and many other hygienic regulations daily printed and published, it is satisfactory to know, through the press, that Turkey at large is in the vanguard of sanitation, and her sanitary motto is "Excelsior." Why should it be otherwise—a few queerly suggestive smells here and there notwithstanding?

The season of "Villeggiatura" is almost over, when the fashionable world and its doctors will return to town. The meetings of the Imperial Society of Medicine have been resumed. A discussion on the contagiousness of leprosy is forthcoming. It may be both useful and interesting if Dr. Zambaco takes part. Quarantine against plague no longer exists, so far as Constantinople is concerned.

RELATION OF SEA-SICKNESS TO VERTIGO.

To the Editor of the Medical Record:

Sir: Referring to the article by Dr. E. Costelli of Washington, D.C., in the Medical Record, of October 11, 1902, I beg to say that, as far as the idea of the relationship of sea-sickness to vertigo is concerned, he is most probably correct, but it is not a new theory. Gowers, in "Diseases of the Nervous System," 1898, says, in the chapter on Vertigo, "It probably underlies the pathology of sea-sickness, in which the vomiting may be simply a reflex effect of the unaccustomed oscillations of the endolymph in the semicircular canals."

In vertigo, disturbance of the endolymph produces the apparent oscillations of objects; in sea-sickness the oscillations produce the disturbance in the endolymph. In both vertigo and sea-sickness the subjects close the eyes to shut out the painful sense of movement, both of objects and their own bodies.

In minor degrees of seasickness and vertigo there is a sense of swaying and of nausea, but not actually prostration and vomiting. J. E. Courtney, M.D.

Denver, Col., October 20, 1902.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 30, 1902.

A Report of the Blood Examination in Ten Cases of Severe Burns of the Skin.—Edwin A. Locke gives his conclusions as follows: (1) The blood flows sluggishly and is of a peculiar dark, purple appearance. (2) There is an immediate increase in the number of erythrocytes, in severe but not fatal cases, of from 1,000,000 to 2,000,000 per c.mm. within a few hours; in fatal cases, of from 2,000,000 to 4,000,000. (3) A rapidly increasing leucocytosis constantly occurs; in cases ending in recovery often of 30,000 or 40,000 per c.mm., in fatal cases usually above 50,000 per c.mm. (4) Morphological changes in the erythrocytes are slight. (5) The percentage of neutrophiles is somewhat above the normal, but not so much as in the ordinary inflammatory leucocytosis. (6) A considerable destruction of the leucocytes takes place, especially in the very severe burns. (7) Myelocytes may be present in small numbers in severe cases. (8) There is, as a rule, marked increase in the number of blood plates.

A Case of Ununited Fracture of the Radius Due to Osteomyelitis.—Charles F. Painter reports the case of a child of six years in whom acute osteomyelitis with trauma was mistaken for green-stick fracture, and was rendered a complete fracture. Union did not occur, in spite of operative treatment, and this condition of things went on for more than two years. Finally, after constitutional treatment for several months, a seventh operation was performed, the diseased bone was refreshed, and enough of the sound bone excised to compensate therefor, and the bones were sutured. The result was excellent. Union was apparently solid at the end of two months; there is now a moderate degree of bowing of the ulna backward when the forearm is held supinated. Pronation and supination are normal, and the functional result is perfect. The arm is, of course, shorter and slightly smaller, as is also the hand on this side. The author says that he is aware that this compensatory shortening of bones in cases of this sort is no new procedure, but the case is recorded as being of interest in connection with this subject.

Journal of the American Medical Association, Nov. 1, 1902.

Some Physiological Factors Involved in the Origin of Scurvy.—R. R. Rogers summarizes his views as follows: (1) The direct cause for the appearance or continuance of an attack of scurvy does not depend upon the activity of microorganisms, although the latter may establish conditions favorable to the onset of scurvy or aggravate a case already existing. (2) The direct cause for the appearance or continuance of an attack of scurvy lies in the establishment of the condition known as "lack of oxygen" in the tissues. (3) Those conditions which tend to prevent the formation of acid, *i. e.* of hydrogen ions (and possibly other products also), in the tissues and tend to increase the store of available alkalinity, *i. e.* hydroxyl ions, in the blood and lymph, are the conditions most antagonistic to the development of scurvy or its continuance, and those most favorable to its cure.

Principles Controlling Operative Interference in Strabismus.—E. Jackson says that the first question to be asked concerning a proposed operation is, how will it influence the innervation of the muscles acting on the eyeball, or will it leave that innervation quite unaltered? According to the answer given this question, strabismus cases are to be divided into two classes: (1) Those in which operation is likely to modify the innervation, as in concomitant squint, in which it will render possible binocular fixation; and (2) Those in which it is not likely to modify innervation, as in paralytic strabismus or in concomitant squint in adults. In these cases operation should be deferred until the extent of duration has become fixed and incapable of further favorable modification by non-operative measures. In case of paralytic squint, this will be months, or even years, after the occurrence of paralysis. For concomitant squint it will be only after the most thorough trial of appropriate lenses and exercises calculated to modify the innervation of the muscles, and not until the years of early childhood have been passed, or possibly not until adult development has been reached. In any such case the time for operation will be not until long observation has shown that the deviation is quite constant, or that the limits within which it varies are stationary. When such a permanent condition is to be altered by operation, the operation should aim at the most exact mechanical adjustment of the visual axes possible, with proper consideration of probable cicatricial changes, and an allowance for slight tendency toward divergence with increasing age, in eyes removed from the influence of binocular coordination and excessive accommodative effort. The author also calls attention to the fact that the effect of the setting forward or backward of muscular insertion on the eyeball may be nullified by changes occurring in the muscles themselves. Thus, the muscle, the influence of which is supposed to have been diminished by tenotomy, might under the needful nerve impulses, undergo an hypertrophy that would restore the excess of influence it had lost. Unintended effects of operation may cause a similar result. Thus, after advancement, a firm adhesion between the advanced tendon and the sclera may cause the muscle to exert its influence on the globe farther back than its original insertion, and thus cause a limitation rather than an extension of its influence. Finally, the effect on rotation of the different muscles must be considered not in its singularity but in its relation to the action of other muscles. An ocular muscle turns the visual axis toward its insertion only when the direction of its action and the visual axis lie in the same plane.

Medical News, November 1, 1902.

Parasitic Amœbæ.—Frederick G. Canney declares that while the occurrence of the amœbæ in malignant tumors is an interesting coincidence, and while there are many reasons for suspecting an infectious agent in certain cases, we must as yet be satisfied to accept the possibly rather unsatisfactory theory that the cause lies in some unexplained stimulus causing epithelial tissue to proliferate and infiltrate in an unnatural manner, mesoblastic as well as epiblastic, and hypoblastic tissue. While the parasitic theory satisfactorily explains many of the primary growths, it fails to show why epithelial tissue proliferates in a locality where it has no normal habitation, as in metastatic growths occurring in mesoblastic tissue. The amœbæ which the writer has seen have almost always been situated in a vacuole. The relation of these parasites to their host is problematical. The amœba multiplies by sporulation.

Ocular Vertigo.—Wilbur B. Marple states that by far the commonest cause of ocular vertigo is the diplopia following a paralysis or paresis of some nerve supplying the ocular muscles. Diplopia is, however, often met with unassociated with vertigo. Two points regarding diagnosis are referred to by the writer: The less conspicuous the [illegible] anomaly [illegible] to the observer. [illegible] the patient to suffer from vertigo, the failure of the vertigo to disappear when one eye is closed does not necessarily exclude the possibility of the existence of some muscular anomaly of the eye. The following safe rule is given: If closing one eye does not cause a disappearance of the vertigo, then have the patient close the other eye only. If there is a paralysis or paresis of an ocular nerve the vertigo will then disappear at once. After excluding any paralytic muscular anomaly, the writer declares that his expectations of finding any ocular cause for the vertigo are very much lessened. He believes that the influence of insufficiencies of the ocular muscles in the production of various disturbances has been vastly overestimated, and that a great deal of injudicious snipping of the ocular muscles has been done. He has met with not a few cases of vertigo associated with ocular palsy, but the number in which a muscular or refractive anomaly of the eye was the cause has been very small.

Report of Ninety Cases of Typhoid Fever in Infants and Children.—Isaac A. Abt presents this report. Typhoid fever in children under two years of age is extremely uncommon. It can hardly be doubted that fetal typhoid can occur. Headache was the most frequent prodromal symptom. In the younger children the pulse was rapid, while in the older children it was slow. There is nothing new to note from the temperature records. Relapse occurred in 10 per cent. The onset of the disease is often characterized by the occurrence of nervous symptoms. Infection of the mouth occurred despite the greatest care. The writer takes up the various symptoms, after which he considers the organs. But perhaps the most interesting feature treated is the urine. Out of ninety specimens of urine, representing fifteen cases of typhoid fever, seventeen specimens, representing five cases, showed the presence of the typical typhoid bacillus. In eighteen specimens, varieties of the bacillus coli and of the typhoid germs were found. In the greater number of cases the typhoid organisms were first found from the end of the third week to the middle of the fourth week of the disease. They may, however, make their appearance as early as the end of the second week, or as late as the fortieth or forty-fifth day. The typhoid bacillus, when accompanied by other species, may occur in such small numbers as easily to escape notice. The bacilli may be so numerous as to make the urine turbid. The largest number is more likely to be found just after the height of the fever, or at the beginning of the defervescence, from which time they usually decrease in numbers as long as the examinations continue. In Abt's cases in which the typhoid bacillus was found, albumin was always present. In the cases in which the typical typhoid bacillus was found, pus could nearly always be demonstrated, even though, in many cases no pus microbes were present. Prophylactic measures should be taken in these cases. Rigid disinfection of the urine should be made from the first appearance of the bacillus till it disappears. The administration of small doses of urotropin to the patient is one way of accomplishing this result. The treatment employed in these cases was the same as that which is everywhere in vogue.

New York Medical Journal, November 1, 1902.

The Dependence of Skin Affections upon Nutritive Disturbances.—W. R. Inge Dalton finds the acid dyscrasia to be the starting point of many skin troubles, and insists upon the necessity of daily evacuation of the bowels, abstinence from alcohol and malt liquors, absolute avoidance of sweets, no meat for six weeks, though fish and eggs are permitted and copious draughts of water, especially before breakfast. He favors the use of the following combination, in tablet or capsule: naphthalin, one grain; ipecac, one-half grain; willow charcoal, one and one-half grains, and one one-hundredth grain each of calomel, strychnine and pilocarpine.

The Burke Foundation and a Plea for Proper Homes for the Convalescent Poor of the Large Cities.—S. A. Knopf suggests that on the foundation recently established by Mr. Burke there should be erected the following institutions: (1) a home for patients convalescing from nervous diseases; (2) a convalescent home for patients discharged from obstetrical and surgical wards; (3) a home for convalescents from typhoid fever, pneumonia, grippe, rheumatism, etc., and (4) a home for convalescent consumptives. All four institutions should be in different localities and at some distance from each other, for the aggregation of too large a number of people would prove injurious to no matter what class of convalescent patients. If at all practicable, each home should have a division for convalescent children.

A Case of Necrosis of the Mucosa of the Large and Small Intestine, with Hemorrhage into the Tissues, Produced by Streptococci (Enterococci).—The case is reported by H. F. Harris, the patient [illegible] suffering from eclampsia. [illegible] and a dead child was removed. The patient died two days and a half after the operation, apparently from exhaustion. The autopsy findings are recorded with the most painstaking minuteness and the record cannot be reproduced here. The author believes that, in view of the fact that the patient was suffering from Bright's disease, it seems highly probable that the condition of [illegible] resistance in the body resulting from the renal lesion was, in a large measure, responsible for the pronounced character of the changes observed in the intestine.

American Medicine, November 1, 1902.

Arthropathy of the Vertebral Column in Tabes.—William G. Spiller reports this case of tabes dorsalis in a patient aged fifty-nine years. She first noticed, about four years ago, that her spinal column was being deformed. She has pronounced scoliosis and lordosis in the thoracicolumbar region, and this deformity is said to have developed gradually. The right hip is raised considerably higher than the left when the patient is sitting on account of the deformity of the vertebral column. The spinal arthropathy is associated with arthropathies of the left foot, left knee, and right shoulder, and an arthropathy is probably now developing in the left shoulder. According to Marie, it may be very difficult to determine whether the condition is one of fracture or arthropathy of the vertebras and possibly the two conditions exist together. Arthropathies of the vertebral column in tabes are of very rare occurrence.

The Causes, Prevention, and Cure of Puerperal Eclampsia.—Robert Reyburn states that after the initial stage of nausea in pregnancy, the appetite is apt to become abnormally keen when the patient eats too largely. Many physicians are accustomed to prescribe alcoholic drinks at mealtime for these patients—a reprehensible practice. Two other factors in relation to the causation of the disease under discussion are neglect of sufficient exercise and neglect to keep the skin in proper condition by bathing and friction. Preventive treatment is far more important than remedial. Purgatives and diuretics are indicated in cases of albuminuria. Hydrotheraphy and diminution or total abstinence from nitrogenous food help wonderfully in the treatment. If convulsions develop during labor, delivery should be accomplished as quickly as possible. Bleeding is sometimes indicated, as in a case of the writer's, when the convulsions came on after the delivery of the child. When the disease develops during the early period of pregnancy, the writer recommends that all other methods of treatment be tried before premature labor is induced. The skin, bowels, and kidneys should be made to act vigorously. Elimination is the keynote to the whole situation.

Why Do the Stomach and Pancreas Not Digest Themselves? Howard B. Baker suggests the following theory. The "secretions" that are manufactured by cells are substances that they do not need—are, in fact, their excretions. Bacterial cells are poisoned and their processes brought to a standstill by accumulation of the products of their own activity. It is probable that this is more or less true among living things. It would seem from Beaumont's observations that the stomach is normally empty without food. If this is so, then undiluted gastric juice does not normally lie on the lining membrane of the stomach. When it is being produced the food is in the stomach and takes it up and carries it away. Long before there is an over-accumulation, the cell begins to be depressed by its own products and to pour them out more slowly. If they still accumulate, the cell is paralyzed altogether, its excretion stops, and this before the product has become strong enough to do any damage to the cells at the place of its formation. The essential idea is that in the glands there is an inhibition of cell activity when the normal excretions accumulate. The relation of this theory, like that of others, to the pathologic autodigestion of the organs of digestion mentioned, is most interesting. If vitality of the part were lost, it is probable that a degree of accumulation which would only slightly inhibit a vigorous living cell would be able to digest it. Or, under the influence of excessive nerve stimulation, the cells of a part of a gland may overwork, and be suddenly overwhelmed, killed and digested. This may explain some cases of pancreatitis.

The Philadelphia Medical Journal, November 1, 1902.

Report of a Case of Penetrating Wound of the Heart; Unsuccessful Attempt at Suturing.—John H. Gibbon saw this patient about half an hour after he had been stabbed. Blood was slowly oozing through the wound in the fourth costal cartilage. The pulse was so small and rapid that it could not be counted. There was no evidence of blood in the pleura. The patient was semiconscious, and any manipulation produced a state of great restlessness. A hypodermic of morphine and atropine was given, but a small amount of chloroform was found necessary in order to proceed with the operation. A flap was turned back and the fourth costal cartilage excised. Considerable semifluid blood was found outside of the pericardium. The opening in this sac was readily found, and, when it was enlarged, a stream of dark blood spurted out. The pericardium was filled with blood. The tip of the finger discovered the opening in the heart, and controlled the bleeding. The third costal cartilage was resected. A catgut suture was passed into the heart near the wound, for the purpose of bringing the organ up into the external opening where it could be sutured. But at this juncture the patient died. The wound was found to be in the right ventricle, just below the pulmonary opening and very near the septum.

A Contribution to the Study of Nephritis in Smallpox Based upon Analyses of Urine in 128 Cases.—William M. Welch, Jay F. Schamberg, Holder C. Kirby, and Russel R. Jones conclude that: (1) Albuminuria is more common in smallpox than is generally believed, having been present in 65 per cent. of the cases examined. The fact that tube casts were found in 45 per cent. of the cases warrants the assertion that the albuminuria in most cases is the expression of a structural change in the kidneys. (2) Cases of discrete variola and well-marked varioloid have, in the experience of the writers, been accompanied with nephritis almost as often as cases with more profuse eruptions. This would suggest that the kidney involvement is the result of the influence of the smallpox poison. (3) The daily fluctuation in the presence of the abnormal urinary constituents necessitates repeated examinations in order to avoid misleading results. Microscopical examinations of the sediment will frequently reveal the presence of tube casts when albumin is not present in quantities demonstrable by the ordinary tests. (4) The clinical symptoms of variolous nephritis are, as a rule, mild, and by no means as obvious as those observed in scarlatinal nephritis. (5) Arnaud's investigation demonstrates that albumin may persist in the urine in minute quantities after convalescence from smallpox. This occurred in 75 per cent. of his cases. The histological examination of the kidney would indicate that this minimal albuminuria represents interstitial changes in the kidney. (6) If it be true that the albuminuria accompanying infectious diseases is, in large part, the expression of a structural change in the kidneys, is it not probable that the damage thus done may, if unrecognized and uncared for, insidiously eventuate in chronic Bright's disease? (7) The practical lesson which is contained in this proposition is that the urine of patients convalescent from infectious diseases should be carefully and repeatedly examined, and the diet and mode of life of the patient regulated accordingly.

The Lancet, October 25, 1902.

Strangulated Hernia in a Woman Ninety Years of Age; Operation; Recovery. The case is reported by E. F. M. Neave, and is of interest from the age of the patient and the duration of the strangulation, which had lasted fifty-two hours. Owing to the slight symptoms of the immediate seizure the friends of the patient would not consent to earlier intervention. The hernial sac was opened and found to contain very little fluid. The bowel looked fairly healthy. The constriction was found to be at the crural ring. The tip of the little finger could not be passed into this opening. With a probe-pointed bistoury the stricture was notched, and the bowel, after being carefully washed with lotion, was pushed back into the abdomen. The sac was dissected up, ligatured, and cut off. The wound was closed with a continuous catgut suture and a carbolic gauze dressing was applied. Recovery was rapid and uneventful. Stitches removed on the tenth day. Ten days later the patient was going about as well as ever.

Mental Dissolution the Result of Alcohol.—R. Jones discusses the distribution of alcohol, its general effects, and quotes certain statistics of the relations between alcoholism and insanity. Acute alcoholic insanity presents a rapid course and a short duration. Chronic alcoholism implies an altered nutrition of all the tissue, particularly parenchymatous elements and epithelium, such as that of the blood vessels, causing thickening and ultimately fibroid changes. The degeneration of the tissue—nervous and non-nervous, consequent upon altered nutrition—is so general and far-reaching that the resulting symptoms are of a most varied nature. Attempts have been made to differentiate these according to the particular form of alcohol taken—such as wines, beer, spirits, liqueurs (absinthe), etc., but the distinction is less psychical than physical, and the symptoms consist in the greater frequency of convulsive discharges from such as absinthe, of analgesia from wines, and of hyperalgesia from essences. The liver of the spirit-drinker is familiar, as also the gross fatty changes in beer-drinkers. Modifying factors are (1) diathesis, idiosyncrasy, or inheritance of the patient; (2) sex (effect-worse in women); (3) elimination depending on eliminative activity and varying in each individual, (4) exercise, and (5) age. The period of greatest incidence to the pernicious effects of alcohol corresponds closely with that period upon which falls the greatest mental strain. The author discusses the symptoms of alcoholic insanity, pathology of chronic alcoholism, and treatment of the insanity, but nothing new is presented under these headings.

A Remarkable Case of Pneumothorax.—The patient of H. C. L. Morris was a man thirty years of age, who fell some twenty feet. Examination showed traumatic emphysema over the left side from the clavicle to the lower-rib border. The left chest was very nearly immobile, and the general signs and symptoms were those fo lung penetrated by a fractured rib, but at no time could a trace of the fracture be discovered. Shortly after, an unusual sound was heard on auscultating the chest. It was synchronous with the cardiac systole. It was someting between a click and the noise made by a bursting bubble, and was distinctly heard all over the room. On auscultation, in addition a loud to-and-fro churning sound was heard over the præcordium. The subcutaneous emphysema was distinctly less, but no breath sounds could be heard. The patient had very little discomfort, his temperature was normal, and his pulse was 68 and of good volume. Indeed, during the whole course of his illness the temperature never rose above normal, neither did his pulse-rate after the first day range above 70. The clicking sound was audible to those standing by the bedside for four days, and was always worst when he turned on to his left side. The subcutaneous emphysema had disappeared by the third day. On the fifth day breath sounds were faintly heard over the apex, and gradually became louder each day until the fourteenth, when the lung had fully expanded. The sounds heard over the præcordium—namely, the clicking and friction sound—remained very loud until the seventh day, and then got fainter and were last heard on the tenth. Morris thinks that they were caused by the squeezing of bubbles of air between the pericardium and the parietal layer of the pleura. Most certainly the man had no pericarditis. A fortnight after the accident the chest presented no abnormality whatever and a week later the man returned to work perfectly well.

The British Medical Journal, October 18, 1902.

The Therapeutic Value of Arsenic and the Justification of Its Continued Use in the Light of Recent Observations Concerning Its Toxic Action.—Ralph Stockman believes that the occurrence of serious chronic arsenical poisoning as a result of the medicinal administration of the drug is decided rarity, and happens very seldom in ordinary medical practice. There is practical unanimity of opinion that serious effects very seldom accompany or follow its therapeutical administration. However, Jonathan Hutchinson holds that the prolonged internal use of arsenic may give rise to epithelioma. The writer speaks of the signal value of this drug in cases of certain chronic skin diseases, in chorea, malaria, asthma, and in chronic heart affections. He has not found it of any use in diabetes mellitus. There is no evidence to show that arsenic has any pronounced effect as a hæmatinic tonic. It is undoubtedly a valuable general tonic. The late researches concerning the value of cacodylic compounds as substitutes for the ordinary preparations of arsenic are discussed. Stockman thinks that it is unlikely that the different chemical compounds containing arsenic are much superior to the original drug.

Pure Urea in the Treatment of Tuberculosis.—Henry Harper declares that urea fulfils many of the requirements of a remedy for tuberculosis. It is not a corrosive, poisonous to the tissues, so that it can be administered in doses sufficiently large (1 to 1½ per cent. body weight) to exert an inhibitory power on the bacillus. It is capable of good, and almost incapable of harm. It is an animal substance, not one foreign to the economy; its action is to supply something that is needed to reinforce the body to resist the invasion of the intruder. In its administration, begin with twenty-grain doses, and gradually increase up to sixty, eighty or one hundred gr., three times daily between meals, dissolved in water flavored with peppermint. If symptoms of gastritis show, then cease the urea for a few days and begin again. It is valuable in all forms of tuberculosis, including that of bone and lupus. In cases of mixed injection the writer has given, along with pure urea, calcium sulphide. Surprising results have been obtained. In proportion as he has increased the nitrogen in [illegible] the death-rate has lessened. In the last year this death-rate has been reduced by 75 per cent.

Exaltation of Bacterial Virulence by Passage Outside the Animal Body.—E. W. Ainley Walker declares that the virulence of a bacterium for a particular species of animal is in general heightened by its growth in the tissues of an animal of that species. The usual method for increasing the virulence is that of "passage" through a succession of animals. The writer has carried on experiments by growing a particular variety of typhoid through fresh (bacteriolytic) normal rabbit's blood for nearly thirty passages, and noting the effect upon its virulence. The virulence of the organism for guinea-pigs was at least doubled by twenty-six passages through fresh rabbit's blood. In regard to rabbits, the virulence was more than doubled by a passage through fresh blood of the same species of animal. The writer concludes that: The virulence of a bacterium may be increased by "passage" through a bacteriolytic fluid *in vitro*. The practical bearing of this observation and its relation to certain of the problems of infection and immunity are apparent. The increase of bacterial virulence, which may be brought about by "passage" through the body of a living animal, is probably attributable to the effect of the successful resistance of the surviving microorganisms to the bacteriolytic action of the living tissues.

On the Use of Alkalies in Relieving Pain. Lauder Brunton calls attention to the fact that the presence of acid in a carious tooth is a most potent cause of toothache. Dyce Duckworth has shown how toothache may be stopped as if by magic by putting into the cavity a little cotton dipped in sodium bicarbonate, thus neutralizing the acidity. It may be mixed with laudanum or cocaine, or both, or it may be used alone. When pain is felt in all the teeth, it often depends upon irritation of the roots of the teeth, just at the edge of the gums, by acid fluid in the mouth. This pain may be generally be relieved by rubbing a little sodium bicarbonate along the edge of the gums, or by rinsing the mouth with a solution of sodium bicarbonate. The strength is not important. A teaspoonful to half a tumbler of water answers well. The writer then speaks of his own experiences with boils. These were very painful, and he took sodium bicarbonate by mouth with benefit. Later he applied a solution to the boils themselves with the most satisfactory results. He speaks of the more extended use of alkalies in neuralgia. The relief in these cases after taking food not unlikely depends more on the secretion of acid in the stomach and a consequent increase in the alkalinity of the blood than to any change in the circulation. In this case the free use of sodium bicarbonate and potassium bicarbonate in such cases may help to give relief.

British Medical Journal, October 25, 1902.

A Fifth Attack of Scarlet Fever.—A. G. Everard gives an account of a patient who had the fifth attack of scarlet fever. The first attack was at the age of two and a half years; this was complicated with chickenpox and measles, all three rashes being present at the same time. The second attack came at the age of seven, the third in 1887, the fourth and fifth in 1896 and 1901, respectively. The daughter of the patient, ten years old, had her second attack of the disease at the time the mother suffered from her fifth.

Serum Therapeutics and Carcinoma.—William James Hoyten reports two cases of incurable cancer in which he used injections of serum expressed from carcinomata taken from other patients. In one case he mixed the serum with normal saline solution, and in the other he used the plain serum. In both cases the infiltrated glands cleared up wonderfully, and the great pain practically ceased. The writer believes that if the surgeon in general practice could obtain fresh specimens of carcinoma for the preparation of serum, the results would be very happy both for the patient and the profession.

The Harveian Oration on the Heart and Nervous System.—David Ferrier considers his subject in several sections. He first takes up the circulation and the nervous system, and reviews Harvey's work. The subject of visceral nerves next receives attention. These nerves consist of two sets, possessed of opposite functions—motor and inhibitory. These terms are applicable to their action on the heart, blood vessels, and hollow viscera. The writer then brings us down to the time of the brothers Weber, who, in 1845, observed that electrical irritation of the vagus caused the heart to beat more slowly, or even to stop temporarily in diastole. The heart is hardly, if at all, sensitive to tactile stimuli. But it is sensitive to severer forms [illegible] to [illegible] of [illegible] normal tension. The [illegible] part [illegible] the part toward the base. The centers, both of the cardiac accelerators and inhibitors and augmentors are in the medulla oblongata. They are more or less continuously automatically active. As a rule there is no direct voluntary control over the heart. There are cases on record, however, in which the heart's action has apparently been inhibited. Some of these may be explained as occurring through the medium of the respiratory mechanism. In other cases this explanation will not suffice. The caliber of the blood vessels like the heart is regulated by mutually antagonistic sets of nerves, the vasoconstrictors and the vasodilators. The center which regulates the caliber of the blood vessels is in the pons. There is also evidence of subsidiary centers in the cord itself. The centers of the vasodilator nerves have not been determined with the same precision as those of the constrictors. They are probably related to the segments of the cord from which they arise. Vasodilatation is sometimes only a cessation of normal tone. There is one nerve whose action is always vasodilatation. This is the depressor, one of the afferent or sensory nerves of the heart. The writer then discusses the function of the cardiac and vasomotor nerve mechanism. The cardiac and vascular reflexes are intimately connected with the circulation of the brain. No satisfactory experimental evidence has yet been furnished as to the existence of vasoconstrictors or vasodilators of the cerebral blood vessels. However, nerve plexuses like those of vasomotor nerves elsewhere have been demonstrated on the vessels of the pia mater. The cerebral circulation varies, on the whole, only passively with the circulation as a whole. The cerebral circulation depends largely upon the tone maintained by the vasomotor center. The last section considers the influence of cerebral activity on the circulation. This is a very complex problem, which still awaits a definite solution. It has been shown that every feeling, whatever be its nature, acts primarily as an excitant. Vasoconstriction is caused by the passage from a condition of repose to one of activity, whether intellectual or emotional. Wundt holds that the discrepancies are due to the fact that the characters of feeling are far more complex than can be expressed in simple terms of pleasure or pain. Pleasurable states of mind are accompanied by a more active circulation and exaltation of all the vital processes, while the opposite condition exists in a state of mental pain. Under the influence of fear, not only is the circulation affected, but there is a tendency to irradiation beyond the cardiac and vasomotor into all the splanchnic functions. Various phenomena, such as profuse perspiration, horripilation, etc., are the result of its action. It is not accurately known through what channels the cerebrum influences the cardiac and vasomotor centers, but they probably traverse the tegumentum beneath the corpora quadrigemina.

Deutsche medicinische Wochenschrift, October 9, 1902.

Hæmolytic Blood Plasma.—G. Ascoli, after a series of experimental observations, comes to the conclusion that the blood plasma possesses the same hæmolytic properties which have been demonstrated in the blood serum [illegible] vitro and in vivo. When all the facts are taken into consideration, it is improbable that hæmolysis is an [illegible] process or dependent upon plasmolysis or [illegible] and it seems certain that it is due to the combined action of two ferments, known respectively as the immune body and complement, which are present in the blood plasma and are not encountered in the serum as the result of [illegible] tion, leucolysis, or post-mortem changes.

Cutaneous Gangrene Following Subcutaneous Infusions.—E. Wormser does not agree with Baisch that the cutaneous gangrene, which the latter observed after the subcutaneous injection of Tavel's solution, is due to the [illegible] which is contained therein. Wormser [illegible] used subcutaneous infusion in upward of [illegible] cases; in about one-half of these Tavel's solution was employed and in the rest a saline solution. Two cases of cutaneous [illegible] were observed, one following Tavel's and the other following the salt solution. Certainly, upon this basis, [illegible] be said that the soda in Tavel's solution is [illegible] of cutaneous gangrene and it is certain that in the [illegible] which it is present other factors are responsible [illegible] appearance that have as yet been discovered.

Penalties for Drunkards.—The Austrian Government [illegible] preparing a bill for the purpose of combating drunkenness. The measure provides for the imposition of severe penalties upon dipsomaniacs.—*New York Tribune.*

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Proceedings of the Twenty-eighth Annual Meeting, Held in Kansas City, Mo., October 15, 16, and 17, 1902.

The association met at the Midland Hotel, under the presidency of Dr. S. P. Collins of Hot Springs, Ark. After the reading of the reports of the secretary, treasurer, Committee on Credentials, Committee on Publication, etc., the president delivered his address.

The Relationship Syphilis Bears to the Body Politic was the title of the presidential address. His reasons for selecting this subject were, first, because of the importance of calling attention constantly to a disease so widespread as syphilis; second, because it was a disease which, with proper education concerning its frequent occurrence, together with its various modes of transmission, could be controlled more effectively than most diseases, and, thirdly, because for the past twenty-five years he had been a daily observer of its frightful ravages upon the body politic or society at large.

The history of syphilis was so closely interwoven with the history of the world that it was difficult to disassociate the one from the other. From the earliest records kept by the Chinese and Hindoos down to the records of the Greeks and Romans, a disease characterized by a primary sore, followed by constitutional symptoms, had existed. Anthropology had demonstrated that an affection was present among men in prehistoric times which produced lesions corresponding with those found to-day in tertiary syphilis, and in the inherited forms of this disease. Records showed that 4,526 years ago the Chinese knew of the duality of the chancre. They also knew that mercury was the antagonistic medicine, and syphilis existed among the Jews centuries before the birth of Christ, assuming such proportions at one time that Moses had 24,000 men who had contracted it summarily put to death. With the outbreak of the epidemic of the fifteenth century, the disease seemed to have assumed a malignant form, the general characteristics of the affection becoming apparently more pronounced and malignant. The prevention of the spread of syphilis, in the author's opinion, by educating the public more thoroughly as it is being educated concerning the communicability and modes of transmission of tuberculosis, should be more vigorously advocated. The public, however, must first be willing to learn before it can be taught.

Syphilis was communicated not only by some infected person, but by articles which have come in contact with the specific poison, and kissing was a prolific source. Bulkley had shown it could be conveyed by knives, forks, cups, pipes, cigars, chewing-gum, and candy passed from one person to another. A new-born babe, with inherited syphilis, was extremely infectious to those about it. The history of this disease was intimately associated with the subject of prostitution.

In our day the prohibition of prostitution was not practical. Regulation of the vice had proved ineffectual in controlling its spread. If it was legalized, the men frequenting the houses should be subjected to the same rules in regard to examination that the unfortunate inmates were subjected to. In New York City there were, in 1901, about 200,000 cases of syphilis, and Gihon, a few years ago, estimated that there were two million cases in the United States. Syphilis was prolific of harm to humanity; its dire results were far reaching; it was no respecter of persons, being as vicious in the palace as in the hovel, and physicians could do more by educating their patients as to the modes of infection, and by advising with the younger ones among those whom they treat, than all the laws that had been or will be enacted could do to prevent the spread of syphilis.

The association divides its scientific work into two sections, medical and surgical.

MEDICAL SECTION

Smallpox.—Dr. John M. Batten of Downingstown, Pa., read a paper on this subject, in which he detailed the symptoms, and then discussed the diagnosis, prognosis, and emphasized the necessity of vaccination.

An Attempt to Obtain Uniformly Active, Sterile, and Non-Irritating Preparations of Digitalis for Subcutaneous and Internal Administration.—Dr. E. M. Houghton of Detroit, Mich., referred to the unsatisfactory condition of our knowledge of the chemistry of digitalis, and stated that a sterile, non-irritating, and uniformly active preparation was greatly needed. He detailed his efforts to obtain such a preparation containing the largest possible amount of active constitutents and the smallest amount of the inert constituents of the drug, based on pharmacological experiments on the lower animals. He gave the clinical results and conclusions arrived at.

Some Developments in the Therapy of Iodoform.—Dr. J. J. Gaines of Excelsior Springs, Mo., followed with a paper on this subject. He regarded iodoform as the best remedy for tuberculosis at the command of the physician. He spoke of it as an ideal iodide, storing all quantities of iodine, which could be easily liberated. He mentioned its use in pulmonary and gastrointestinal diseases, and reported a number of cases in which he had used it with gratifying results.

Normal Sleep Versus Drug Unconsciousness.—This paper was read by Dr. J. B. Learned of Northampton, Mass. Natural sleep was indispensable to long life and business success. Drug unconsciousness, labeled sleep, was the reverse. The indoor brain-worker failed to lay the foundation of normal sleep by day, and suffered by night the result thereof. Brain and muscle employed in the open during the day would secure the normal conditions of sleep at night. Automatic brain activity at the sleeping hour was the immediate cause of wakefulness. The ready remedy was muscular exertion under the direction of the will, either mild, without change of parts, or the reverse. Control of the respiratory and circulatory functions met the desired end by withdrawing power from the brain centers. All automatic brain work was suspended when concentrated attention was paid to alternate contraction. and relaxation of certain groups of muscles. Automatic brain work was pathological. Brain and muscle work, under the direction of the will, was physiological. The author detailed a method of inducing sleep.

The Treatment of Exophthalmic Goiter by Electricity.—Dr. H. M. Beaver of Spring Hill, Kan., in this paper defined exophthalmic goiter, and then discussed the clinical history, cause, etc. He said predisposition might act as a predisposing cause. The exciting cause might be a previous illness, injury, or over-exertion. The exciting cause involved a determination of blood to the brain and medulla oblongata. This determination of blood acted as an irritant by pressing upon the nerve centers, causing the incoordinate nerve action found in this disease. The symptoms referable to the heart, lungs, stomach, thyroid gland, and eyes were nervous phenomena. The cardinal principle of treatment was to decrease the flow of blood to the head. When this was accomplished, all the minor symptoms would subside. The author reported three cases of the disease, and described the mode of application of electricity, also the battery used. He regarded exophthalmic goiter as a vasomotor paralysis; hence it was amenable to electrical treatment.

Symposium on Tuberculosis.—Dr. W. A. Campbell of Colorado Springs, Col., read a paper entitled "What Class of Pulmonary Cases Do Well in Colorado?" After speaking of the prevalence of tuberculosis and the frequency of unrecognized and cured cases as shown by autopsies, Dr. Campbell gave an analysis of 250 cases coming under his observation, in which his examinations were made soon after their arrival in Colorado. He found in this series of cases that the average age was twenty-nine and four-fifths years. Sex or social station made no difference in physical condition or result. Twenty-nine States and five foreign countries furnished the cases. Those with tuberculous family history did not do as well as the non-tuberculous. The percentage of benefited decreased as the duration of the disease increased. The right lung was involved alone oftener than the left. The percentage of benefited was slightly in favor of the right lung. Where both lungs were involved the mortality was 50 per cent. In the first-stage cases 92 per cent. were benefited; in the second stage, 54 per cent.; in the third stage, 13 per cent. Hemorrhage, occurring in the first stage of the disease, was no contraindication to residence in high altitude. The diminished arterial tension and dilatation of external capillaries, due to lessened atmospheric pressure, made it safe for hemorrhagic patients to seek a higher altitude. He would not send patients of acute military tuberculosis or phthisis florida to high altitudes; neither would he send the extremely nervous, with an irregular or rapid heart and high temperature. Patients with well advanced disease, with rapidly breaking-down lung, should not come. Those having cardiac dilatation or acute endo- or myocarditis should not come. Cardiac murmurs were no contraindication if compensation had taken place. Those having Bright's disease should not come. Those with advanced laryngeal or intestinal disease did not do well. He would have patients come with sufficient money to support themselves on good food until acclimated and improvement was well advanced. In conclusion, he cited the high percentage of cases benefited in the first stage, and made an appeal for the early detection and early protection of the tuberculous subject.

Climatic and Electric Peculiarities of Colorado Favoring Recovery in Pulmonary and Intestinal Diseases and from Surgical Operations.—Dr. J. E. MacNeill of Denver, Col. followed with a paper on this subject, in which he discussed the physical characteristics of Colorado affecting its climate; the mineral springs of Colorado, and cited some generally-accepted facts regarding mountain climates applicable to Colorado. He also discussed the value of high altitudes with their rarified air and direct sunlight in the treatment of abnormal conditions, and, finally, the electric conditions.

Digestive Disorders in Consumption, with Notes on Mixed Infections.—Dr. Paul Paquin of Asheville, N. C., regarded consumption as a mixed infection, and the plague of civilization. The majority escaped this disease, not because they were not attacked, but because they resisted the attack. Here was a problem of protection. A condition that would prevent the germs of consumption from developing in the system, and if they did get a start in growth, a condition that would stop them. The digestive apparatus was the system on which the vital energy chiefly depended. If it did not carry on its functions with sufficient effectiveness and persistency, life was a nightmare, and when an individual was sick recovery was a serious problem.

So with respect to consumption, the most vital question was that of nourishment, whereupon one might base such measures of treatment as might be deemed best for restoration. Without nourishment of a sufficient kind, in quantity and quality, nothing would avail in therapeutics. Tuberculosis could not be arrested without the assimilation of sufficient and proper food. Bearing in mind the pathology of the gastrointestinal affections accompanying consumption, a normal condition of the mucosa must be restored before good digestion can take place. Among the local measures to this end were stomach and high intestinal lavage. He had known patients who were declining steadily from the ravages of consumption and dyspepsia to gain from two to four pounds a week after the beginning of weekly or semi-weekly lavage of the stomach alone.

As specific measures, serotherapy, the cacodylates and iodine offered the greatest aid in preventing organic changes. Immunizing antitubercle serum was effective, because it was antagonistic to the tubercle toxins, which were, in a large measure, responsible for such lesions.

Mixed infections in tuberculosis offered the greatest complexity in the dyspepsia accompanying them. He thought it was due to the effect of a combination of the numerous kinds of germ poisons produced in such cases, both in the lungs and alimentary canal.

Excellent Results in the Treatment of Disease, Especially Tuberculosis, by the Use of the Ultraviolet Ray.—Dr. Albert E. Sterne of Indianapolis, Ind., read this paper. He spoke of the division of the sun's rays, dwelling particularly upon the actinic or chemical rays of light, and the identity of those emitted from the voltaic arc with those of the solar planet. From this he had elaborated a method of treatment, for which it was claimed that most excellent results had been attained, both in a general and local manner. The nude body was exposed to intense light from powerful voltaic arcs, and, in addition, free ozone was developed from a special ozonating apparatus. In local applications only one pole was used, and this was connected with vacuum tubes devised for different portions of the body to be treated.

Dr. Sterne claimed most excellent results in almost all conditions of debility, notably in neurasthenia, and in the primary stages of tuberculosis.

His conclusions are: (1) Actinic rays are chemical in their quality, but of small caloric value; (2) They exist mainly in the ultra-violet zone of the spectrum; (3) Actinic rays derived from high power electric lights are similar or identical to those of solar origin; (4) Their use is as rational as sunlight itself; (5) Their value lies in their decomposing, but, at the same time, reconstructive, molecular action upon the body tissues, mainly the blood elements; (6) Their activity is enhanced by the generation of ozone in free and nascent form; (7) Their ultimate effect is one of oxidation, and consequently they increase the metabolic changes, thereby augmenting the natural processes of regeneration within the system; (8) Their germicidal action is especially pronounced, on account of the fact that germs can exist in the presence of free or nascent oxygen in either bi- or tri-atomic form.

Sanatorium Treatment of Pulmonary Tuberculosis, and How It May Be Carried Out at Home.—Dr. Robert H. Babcock of Chicago discussed this phase of the subject. He divided the sanatorium treatment into four classes: Pure air, nourishment, or forced feeding, hydrotherapy, and a strict régime or control of the patient's daily life.

The open-air treatment was obtained by the patient being exposed on a balcony or in properly-constructed shutters, where he was protected from cold winds and elements, and kept in the open air, sometimes even when the temperature was as low as 13° below zero. Among the conditions which indicated rest in the open air were progressive loss of weight and cardiac asthenia. When patients had passed out of the stage in which these conditions existed, were convalescing, then exercise was permitted, the exercise being carefully determined by the medical attendant. The nourishment of the patient was carefully selected, not only with reference to a proper proportion of proteids, which should be large, but which also included the proper amount of carbohydrates. Milk, raw eggs, meat, and its varieties, poultry and fish, etc., were articles on which reliance was chiefly placed.

Hydrotherapy played an important part in the treatment. Hydrotherapy was applied for the purpose of stimulating nutrition, toning up the circulatory system, and overcoming the hyper-sensitiveness of the skin, which existed in so many tuberculous patients.

As to the control of the patient, a very important element in treatment, every patient should be controlled from the time he got up in the morning until he went to bed, and this was done by the supervision of a skillful medical attendant and nurse. The temperature was carefully recorded and even the recreations in which they indulged were carefully selected by the medical attendants, with a view to the prevention of excitement, for even mental emotion was deleterious to many of these patients.

Speaking of the home treatment of tuberculosis. Dr. Babcock detailed it at considerable length, saying that the majority of medical practitioners were not fully alive to the importance and value of this treatment, and were not properly instructed in the details or method.

Tent Life in the Treatment of Tuberculosis.—Dr. A. Mansfield Holmes of Denver, Col., read a paper on this subject. He stated that pure air and sunshine were two important factors in effecting a cure of tuberculosis. Tent life was the most important means of securing the advantages of these factors. The author called attention to the essentials of an ideal tent cottage, and gave rules for governing tent life. These who had had no experience with tent life invariably entertained an exaggerated idea of its dangers and inconveniences. A short experience soon dispelled this fear, and patients were, with difficulty, induced to return to an indoor life. Extended experience with tent life in Colorado justified him in making the following deductions: It increased the appetite; improved nutrition, diminished cough; night sweats ceased; sleep was improved; weight increased; fever decreased, and the tendency to take cold was diminished.

A model of the tent cottage adopted by the Rocky Mountain Industrial Sanatorium was exhibited, showing improved methods of construction and ventilation.

Address in Medicine.—This was delivered by Dr. Hugh T. Patrick of Chicago, who selected for his subject, "How Not to Be Nervous." The author stated that the initiative of all therapeutics should be prophylaxis. Prevention was paramount to cure. The first and most effective preventive of nervousness was a reasonably long line of first-rate forbears. To be able to present a specific illustration of the force of inheritance in the genesis of functional nervous affection, he had tabulated from his office records 100 consecutive cases which might be included under the general term nervousness, and he found that in 70 per cent. of them a neurotic heredity had been in evidence. While a bad heredity was the most frequent and most potent factor in the production of nervousness knowledge of this fact should not lead the profession into apathetic resignation, but rather make it face the difficulty with wise determination.

Next to the omnipresent, inevitable laws of inheritance, came the never ceasing formative power of environment. Reaction to extraneous influences began at birth, and ceased only with the extinction of life, but childhood and youth were the plastic stages.

For preventing nervousness in the child, or removing that already present. Patrick thought that there was nothing so effective as the toughening of the body and mind. A child who was made to have tough muscles, strong lungs, and a vigorous digestion, who could stand changes of temperature and endure pain, was already a long way from nervousness. More important still was toughness of psychic fiber. The child who could support disappointment, who could be crossed without a tantrum, and who habitually obeyed, was building a bulwark against nerves, and the one who was not easily frightened, had self-control and a budding courage, had nipped half a dozen neuroses in the bud. But to procure this toughness a certain exposure to bodily discomfort and mental hardship was necessary.

The author discussed at length the prophylaxis of the neuroses in children, and then passed on to the consideration of adult life. He said a deal of nervousness was caused or helped along misdirected energy, misplaced worry, longing for baubles, the fighting of phantoms, etc. To recognize the important things in life was one of the most difficult tasks of judgment that came to the individual.

To sum it all up, the author said: "If you wish never to be nervous, live with reason; have a purpose in life and work for it; play joyously; strive for the unattainable, never regret the unalterable; be not annoyed by trifles; aim to attain neither great knowledge nor great riches, but unlimited common sense; be not self-centered, but love the good, and thy neighbor as thyself."

Neurasthenia.—Dr. George F. Butler of Alma, Mich., read a paper on this subject. Neurasthenia was the expression of nerve tire of the central nervous system and its consequences. Nerve tire of the central nervous system implied acceleration of the action of the excitomotor ganglia of the organ, with first, increased functionating of these organs, and, second, exhaustion with its consequences. In this way central nerve tire, finding expression along the line of least resistance, produced local organ expressions which were claimed as the cause of the constitutional condition. From these local expressions a viscious circle often resulted, which aggravated the original condition. As over-action of the organs implied under-elimination, auto-toxæmia, of necessity, followed nerve tire of a very poisonous type, like all products of nerve waste. From this, renal and hepatic disturbance was added to the clinical picture, and intensified its blackness. Neurasthenia might occur alone, or might be an expression and complication of any constitutional disorder. In such case both the nerve tire and the constitutional disorder required treatment. The neurasthenia resultant on phthisis, nephritis, diabetes and syphilis, was a true neurasthenia, which, if not treated, intensified the disorder which gave it birth.

The treatment of neurasthenia consisted in the relief of the nerve tire and conditions underlying it through proper diet, hydrotherapy, balneotherapy, relief of insomnia, and removal from an etiologic environment. Neurasthenia untreated might produce degenerate offspring, especially if the patient be a woman.

Dr. John J. Taylor of Streator, Ill., detailed a case of rheumatic neuritis, complicated by neurasthenia and other affections.

The Criminal Responsibility of the Epileptic.—Dr. John Punton of Kansas City, Mo., read a paper on this subject, which will appear in a future issue.

Sudden Atrophic Influence of Craniospinal Nerves.—Dr. F. E. Coulter of Omaha, Neb., read this paper. He reported a case and described the areas involved. He also presented a report of normal and abnormal productions, mentioned the possible etiological factors in the case, cited other cases, and then summarized as follows: Under certain conditions craniospinal nerves may exercise a sudden atrophic influence on the skin and the appendages thereof; that the results in the case reported were due to a disturbance of this nature, he thought he was warranted in concluding, because of the following reasons: (1) All the hair was normal before the attack, but within three days after the attack all disappeared from the areas described. (2) The character of the new hair was such as would be the natural product of a faulty nutrition; if due to the production of a toxin or the sudden diminution of the normal elements, was difficult to decide. It was known, however, that the abnormal hair was smaller in size, length, and diameter, and markedly deficient in pigment substance. (3) The fact that this was a bilateral lesion would naturally indicate that one was dealing with a blood condition, possibly a toxin formed by the very sudden and severe convulsive state, which manifested itself on this particular nerve trunk because of some histological character in its decomposition that we, as yet, were unable to detect. (4) That in this particular case we did not have an example of that strange, yet interesting, condition of change in color, a decolorization of the hair seen after a very great fright or severe mental anguish.

which, in a short time, changes the color of the hair completely, but rather a definite nutritive alteration acute in character.

Hebephrenia or Childhood Insanities.—Dr. W. B. Fletcher of Indianapolis, Ind., in a paper with this title, spoke of the causes, character, prevention, and treatment of the various forms of insanity incident to children prior to and during the period of puberty. The writer had observed 300 cases of hebephrenia in the city in which he lived. He cited some interesting cases.

Sympathetic Eye Diseases.—Dr. James Moores Ball of St. Louis, Mo., in a paper on this subject, made a clinical division into sympathetic irritation and sympathetic ophthalmitis. He discussed the diagnosis, symptoms, etiology, prognosis, and treatment of sympathetic irritation. Speaking of sympathetic ophthalmitis, he said it was one of the most formidable and obscure of ocular affections. Only uveal inflammation, which was caused by bacterial infection, could produce this disease. He mentioned the date of appearance, frequency, symptoms, and divided the affection into uveitis serosa and sympathetic fibrinous uveitis, saying that the former was relatively mild, while the latter was a malignant affection. Sympathetic papillo-retinitis, which rarely was the sole manifestation of sympathetic ophthalmitis, was likewise discussed. Other sympathetic affections had been described, without gaining recognition from ophthalmic authorities. He spoke at length on the prognosis of sympathetic affections, and then passed on to a consideration of the pathology and pathogenesis of sympathetic ophthalmitis, discussing the prophylaxis and treatment of these diseases.

Toxic Amblyopia.—Dr. J. W. Sherer of Kansas City, Mo., followed with a paper on this subject. He presented a clinical report of five cases of toxic amblyopia from methyl alcohol that had been seen by him. In all a degree of blindness rapidly followed drinking the poison. The eyes appeared normal externally, with pupils slightly dilated. The media were clear. There were no hemorrhages. Early there were no fundal signs, but later atrophy was visible. The fields were contracted and showed absolute central scotomata. One case was complicated by some involvement of the peripheral nerves of the lower limbs. The pupillary reaction corresponded to the description of Lauder-Brunton, who found it to be the reverse of the Argyll-Robertson reaction. Pathologically, the condition was that of peripheral neuritis affecting the optic nerves or retrobulbar optic neuritis. Much work had been done by different observers to demonstrate experimentally the minute changes. Degeneration of the ganglion cells and macular layers of the retina occurred. This was partly due to vasoconstriction and diminished blood supply, and partly to the action of the poison. Consecutively, the nerve fibers degenerated. In the experiments with quinine there was, synchronously with the onset of the amblyopia chromolysis of the retinal cells, œdema of the pericellular spaces and wasting of the ganglion cells.

Bilateral Glaucoma.—A paper on this subject was presented by Dr. Flavel B. Tiffany of Kansas City, Mo., in which he reported the case of a patient upon whom he had performed double iridectomy.

Diseases Preceding and Following the Use of Alcohol and Opium.—Dr. T. D. Crothers of Hartford, Conn., read this paper. The use of alcohol was regarded by the writer as one of the most subtle and serious causes of disease. Clinical study pointed out many distinct lines of disease which preceded inebriety, of which syphilis, trauma, dementia, and toxic states were most common. Neurasthenic conditions and tubercular diatheses preceded the use of spirits. Atrophic and hypertrophic sclerosis always followed the use of spirits. An early recognition of the organic changes which preceded and emerged into inebriety would enable one to practically prevent the disease.

Treatment of Typhoid Fever with Castor Oil.—Dr. C. C. Bass of Columbia, Miss., in a paper on this subject, reported thirty-two cases of this disease treated with castor oil, and, except in a very few of these cases in which he gave some other medicine to meet some special symptom, he gave nothing else. Thirteen cases were treated with one dose every twenty-four hours, and nineteen cases with a dose every twelve hours. The results following the treatment were very gratifying. He commended this treatment as worthy of further investigation.

Culture of Infusoria.—Dr. Henry G. Graham of Chicago, Ill., followed with a paper on this subject. He discussed the subject under the following heads: (1) Preserving the identity of the individual organism while growing it (*a*) in running water; (*b*) in stagnant water. (2) Isolation of the organism (*a*) by means of the petri dish; (*b*) by feeding to laboratory animals. (3) Transfer of elementary form to fluid culture media. (4) Second transfer of organism to fluid culture media more accessible to the atmospheric air. (5) Favoring growth of skeletal structure of protozoon at the expense of the liquid protoplasm. His deductions were that culture of infusoria will show that (1) Müller's dust corpuscles are elementary infusoria. (2) The exceedingly minute and actively motile forms are derived from the protozoa.

Croupous Pneumonia.—Dr. Wm. T. English of Pittsburg, Pa., discussed some of the signs and symptoms of this affection. He also dwelt at length upon the easiest and best methods of speedily and certainly determining them. He mentioned the application of remedies suitable to the case and stage of the malady, the advantage of grouping some phenomena in securing a speedy diagnosis, and the necessity for observing all signs and symptoms in differentiating diseases with similar manifestations.

Pneumonia.—Dr. Wm. F. Barclay of Pittsburg, Pa., contributed a paper on this subject. He considered the clinical history of pneumonitis; the close relationship between pneumonia and la grippe; the similarity in pathology, initial stages, clinical history, mortality, and treatment. The exciting causes of pneumonia and la grippe were identical. The history, duration, and progress of these diseases differed but little. The two diseases frequently coexisted in the same individual. The affections differed in the structures of the organs affected. He believed a rational treatment was based on a study of the immediate causes of death in pneumonia, as concluded in a large number of death reports in the city of Pittsburg. Heart failure and exhaustion stood out as the immediate cause of death in 98 per cent. of all reported deaths in a circumscribed area of almost one million people. Rest in bed in well-ventilated rooms, apart from atmospheric conditions, was of paramount importance. He had learned from experience that a most decided course of medication was indicated in the treatment of pneumonia, and that a like course of treatment, in cases of la grippe, robbed the disease of its terrors. First, rest in bed with requisite protection from atmospheric influences; second, a thorough cathartic of calomel was essential in bringing about a decisive derivative action of the secretions of the body. Five to ten grains of calomel with thirty to sixty grains of milk sugar, was a formula that had never disappointed him in its beneficial effect. The action of nux vomica, when properly administered, never failed in its power to alleviate the symptoms and afford relief. Tincture of nux vomica should be given in large and frequent doses, well diluted in water.

Treatment of Chronic Dysentery.—This paper was read by Dr. John L. Jelks of Memphis, Tenn. The disease was considered of microbic origin, although a specific organism had not received general acceptance as the sole causal factor. This was the basis of all treatment. No matter what the classification of the disease, the same general idea as to treatment must obtain—namely, the destruction of the microorganism, drainage, cleanliness, rest, and restoration of the tissues. An erroneous idea had prevailed that the disease was beyond reach of any possible topical medication, further than, perhaps, the use of the Wales metal bougie, which was not always a safe procedure. The sigmoidoscope and long rubber tube had a field in the treatment of this affection, and it was necessary to educate the profession as to the possibilities of this method. The patients should be placed in sanitary surroundings, free from unnecessary heat and moisture. The diet should be carefully selected. The stomach should receive careful attention. The portal engorgement should be relieved, and the intestinal tract thoroughly cleansed. Hemorrhage from the bowel, when profuse, could be controlled by styptic enemata given through the double tube. In using the sigmoidoscope, the author recommended the knee-chest position. The bowel should be thoroughly cleansed through this instrument with antiseptic washes, applied very hot. If there was much excoriation or ulceration, nitrate of silver might be applied to bleeding and eroded surfaces with a cotton probang, or in the form of a spray. Higher treatment may be administered through one or two tubes of soft rubber, which can be passed further into the colon, and the antiseptic solution administered by enema through these. If necessary, boracic acid, iodoform, or aristol may be insufflated through the sigmoidoscope, and the bowel thus thoroughly covered.

In the chronic state he had found most benefit from iodoform and ichthyol made into suppositories, and passed through the sigmoidoscope into the sigmoid. This was especially indicated in tuberculous conditions, but had its use in any form of procto-sigmoiditis or colitis. All toxic drugs must be used with caution.

SURGICAL SECTION.

Operations for Cancer of the Mouth and Neck was selected by Dr Geo. W. Crile of Cleveland, Ohio, as his subject for the address in surgery. The author's summary is as follows: In the past three decades there has been a continuous decrease in the operative mortality, and, with a single exception, of the brachiogenic cancers, even a more notable increase in the percentage of cures has been accomplished. Especially in the last decade, there has been evidence of more confidence in operations, as indicated by an increased number of cases submitted early. The supreme importance of early diagnosis, and early and radical operation, is becoming widely recognized. The same may be said of the so-called precancer stage, especially of the tongue. Except in cancer of the upper jaw, the disease is now regarded as involving the regional lymphatic system. The disease may be found in the lymphatic vessels and lymphatic glands. It rarely extends to other parts of the body. Physiological and clinical evidences show that severing the thoracic duct causes but little disturbance, owing to its free anastomosis. That the effect of resection of the internal jugular vein is practically *nil*; that unilateral resection of the vagus does not alter the heart's action, the respiration, nor the digestion, but produces a permanent hoarseness only; that division of the superior laryngeal causes anæsthesia of a part of the larynx, but pneumonia is improbable; that division of the inferior laryngeal causes paralysis of the corresponding vocal cord, but interference with respiration is not marked; that the division of the spinal accessory has but slight effect, on account of the double nerve supply to the sternomastoid and the synergistic action of other muscles; that the division of the hypoglossal causes temporary interference with speech and swallowing, but compensation occurs, that the submaxillary and salivary glands may be removed without symptoms; that the removal of the sternomastoid muscle is not followed by torticollis, etc., on account of the synergistic action of other muscles. The complete removal of the lymphatic system of one side does not produce pseudo-elephantiasis of the face and head. Permanent closure of the external carotid has an operative mortality of 1 to 2 per cent., due to thrombosis and embolism. Permanent closure of the common carotid or internal carotid is attended by an operative mortality of about 3 per cent., but in the cancer period of life from 20 to 30 per cent of cerebral complications follow, about 50 per cent of which prove fatal. Temporary closure of the carotid by means of a special clamp, as shown in the writer's forty-three cases, in which neither death nor cerebral complications occurred, is both efficient and safe. These physiological and clinical data lead to but two objective points in unilateral operations for cancer of the mouth or neck, namely, complete removal of the disease and preservation of the blood supply to the brain. If necessary, sacrifice every other structure between the skin and the place of the deep muscles of the neck. Loss of blood is the greatest operative difficulty and danger. If hemorrhage is likely to be considerable, the common carotid should be closed during the operation. In the mouth cases an anæsthetic may be administered through rubber tubes, passed through the nostrils to the level of the epiglottis, with the tongue well drawn forward. The pharynx may then be packed with gauze, so as to form an air-chamber in the lower larynx effectively, and prevent blood from entering the pulmonary tract. The dissection should be made on the same plan and as thoroughly as in the radical operation for cancer of the breast. The greater ease and certainty with which diagnosis may be early made in this region, and the rarity of extension of the disease beyond the glands of the neck, should enable the surgeon to obtain even better results here than in cancer of the breast. The hope of the patient lies in early diagnosis, early operation, and a logical technique.

Cancer of the Rectum.—Dr. Emerson M. Sutton of Peoria, Ill., read a paper on this subject. He reported cases of cancer of the posterior vaginal wall, penetrating to the submucosa of the rectum, with fibrous but nonmalignant infiltration around the rectum, producing stricture. He operated by the sacral route, resorting to the von Volkmann-Rose incision. He resected the vagina, rectum, and one-half of the cervix, anchoring the healthy end of the sigmoid to the gluteal incision side of the wound. He mentioned other cases from the literature, and then gave reasons for attempting operations for extensive cancerous growths situated in the pelvis.

Treatment of Extensive Rectal Strictures.—Dr. Emil Ries of Chicago pointed out the difficulties in treating these strictures. He referred to septic conditions, anatomical changes, and the danger of recurrence. He discussed anastomosis after resection; end-to-end anastomosis; anastomosis without resection; side-to-side anastomosis after exclusion, and end-to-side anastomosis He detailed his first case, operated upon by the latter method, saying that the patient was well over five years after operation.

Ureteral Catheterism: Its Value in Male and Female.—Dr. Bransford Lewis of St. Louis, Mo., said the purposes of ureteral catheterism in connection with the cystoscope were for diagnosis and for treatment. Cases reported showed that ureteral catheterism, in both male and female, had been reduced to a practical procedure. With the author's cystoscope, the operator was enabled to look directly on the field. Air was used for inflating the bladder. One or both ureters may be catheterized at the same sitting. The operation was performed under local anæsthesia. Case 1 showed the falsity of an *x*-ray diagnosis of stone in the ureter. Case 2 showed chronic unilateral pyelitis and cystitis. Irrigations of the pelvis resulted in a cure. Case 3 was one of tuberculous inflammation of the bladder and kidneys, which improved under irrigations. Case 4, hemorrhagic cystitis and bilateral pyelonephritis; under irrigations of renal pelvis was much improved.

Dr Eastman of Indianapolis thought a removable roof to facilitate withdrawal of the cystoscope leaving the catheter in the ureter would be an improvement

Dr Martin of Missouri found the introduction of the catheter easier than it would seem, and there was no trouble in withdrawing the cystoscope while the catheter was in the ureter

The Mechanics of Intubation.—Dr. B. F. Gillmor of Creston Ia., discussed the mechanical problem of intubation and exhibited drawings and *x*-ray plates. He emphasized the importance of acquiring manual familiarity with instruments; the means by which this may be acquired and then alluded to the problems of intubation and the difficulties of extubation.

Laminectomy for Fracture-Dislocation of the Fourth and Fifth Cervical Vertebræ.—In the case reported, the author, Dr. Joseph Rilus Eastman of Indianapolis, Ind., stated that laminectomy was followed by improvement of motor and sensory conditions, but was unsuccessful so far as saving the life of the patient was concerned. Death occurred on the nineteenth day. After going at length into the literature of the subject the author said that laminectomy for fracture or dislocation should be made early The earlier the better. The longer pressure had existed, the more extensive the degeneration of the cord. Still hope need not be entirely abandoned in old cases, for laminectomy had relieved many such even after months had elapsed since the injury was received. Laminectomy *per se* was not dangerous. It represented the surest method of diagnosis of fracture-dislocation, and the most rational and efficient means of relief.

Dr Stewart of Chicago agreed with the essayist in advocating early operation.

Dr Black of Jacksonville, Ill., advised early operation or exploratory incision. Two hundred and fifty cases operated on, out of a total of 555 cases in the literature, showed 25 per cent. better results than the unreported cases

Extrinsic Traumatisms of the Spine; Their Diagnosis, Pathology, and Treatment.—Dr. Thomas H. Manley of New York read a paper with this title. In this study, all lesions of a traumatic character sustained by the rachidian structures or the medulla spinalis, not followed by clinical manifestations of central complication, were included under the term extrinsic. These were designated (1) contusions; (2) sprains; (3) hemorrhage; (4) fractures; (5) diastasis and luxation; (6) structural and visceral complications. The most frequent injuries, according to the author, were external to the spinal cord. They were rarely of such a character as to seriously impair function, although deformity and impairment of strength occasionally followed. No serious effort had yet been made by an American author to classify the pathology to elucidate symptoms, or to establish the differential diagnosis in this important group of traumatisms.

Spinal Concussion.—Dr. Carl E. Black of Jacksonville, Ill., in a paper on this subject, called attention to the loose way in which the term concussion of the spine was used, and to the unclassified condition of such cases. The best dictionaries were quoted to show that the word concussion is misused, and should only apply to the manner in which the injury was received. A great deal of misunderstanding had arisen from the attempt of various authors to use the word to describe a distinct disorder. The various authors on surgery were quoted to show that there was a misunderstanding among writers as to the scope of the term concussion. The work of Wm. Thorburn of Manchester, England, was quoted as being the only rational effort which had been made to classify these disorders. In conclusion, the author took the position that minute or capillary hemorrhage was the basis of most, if not all, of these cases, and gave the following classification of injuries produced by concussion of the spine: Primary effects—(1) sprains; (2) contusion of the spinal cord; (3) minute hemorrhage into or around the cord. Secondary effects or complications—(1) shock or collapse; (2) acute hysteria; (3) neurasthenia; (4) chronic hysteria The essayist concluded with the following sentence "It is certainly the duty of every surgeon to protect himself, as well as any corporation he may represent and the best interests of his patient, by distinguishing, if possible, between the purely psychical, secondarily psychical, and the truly pathological condition, and treatment should be directed accordingly."

Spinal-cord Injury—So-called Spinal Concussion of the Cord.—In this paper Dr. Frank Parsons Norbury of Jacksonville, Ill., stated that a scientific interpretation of concussion of the cord, so-called, had not yet been attained The term had become established by long usage, and was largely used because of the want of a better term to cover the clinical picture which it aimed to present. The lesion was doubtless a disturbance of the circulation, due to injury to the blood vessels and lymphatics. Intramedullary hemorrhage was thought by the author to be the immediate lesion. This conclusion was supported by the observations of Kocher, Thorburn, and Horsley on the surgical side of the controversy. Neurologists had varied views, some of which were decidedly hypothetic. However, most of them were inclined to the view that structural changes were probable, and that the degenerative and vascular changes, following injury to the cord, were indicated in the symptomatology of the disease. Facts were accumulating which made this view both tenable and reasonable. While many injuries to the cord showed no external evidences, the symptoms which followed indicated structural changes occurring within the substance of the cord, and irritation of the cord roots by meningeal involvement. The symptoms in pronounced cases of hemorrhage were compared to the more obscure conditions called concussion, showing that hemorrhage was common in traumatism of the cord; that similarity of sensory and vasomotor changes existed.

The author said, regarding the psychical element in cord injuries, that it was impossible to eliminate it. It was, therefore, important to recognize the definite and demonstrable symptoms—the symptoms which came on gradually, which, in their entirety, proclaimed the hemorrhagic origin of the disease.

The neuropathology of to-day was leaning toward the organic origin of many diseases heretofore regarded as functional. Concussion of the cord was, in the judgment of the author, one of the most marked of these diseases, and he believed the research work of the future would establish this belief.

The X-Ray in the Treatment of Malignant Growths was the subject of a paper by Dr. Edwin Walker of Evansville, Ind. The *x*-ray had given favorable results thus far. Its exact status must be determined by clinical observation. He reported a case of alveolar melanotic sarcoma of the face, which was removed. The growth returned in two weeks, and had extended to the neck. A secondary operation was performed a month later. There was rapid extension from that time, so that, within a few days, almost the entire neck was involved. The wound had not healed There was immediate improvement after the use of the *x*-ray The wound had cicatrized in two weeks, and all indurations had disappeared at the end of three months. The patient at this time seemed entirely cured. He spoke of the extent of the effects of the *x*-ray on pyogenic germs A test was made both in test tubes and Petri plates, the exposure to the ray being from ten to thirty minutes The results were negative While the *x*-ray was of undoubted value in malignant growths, it should not be adopted to the exclusion of other known methods Excision should be done, if possible, before the *x*-ray treatment was begun

The Physiological Action and Therapeutic Uses of the X-Ray.—Dr C. M. Mutz of Douglass, Kan., followed with a paper on this subject in which he dissented from the opinions of those who believed that the physiological and therapeutic uses of the *x*-ray may be intelligently studied without reference to its nature or genesis. It was not a "giant in chains," which physicians needed to approach in fear when they would unchain it, but no physician, in his opinion, should be content to use a therapeutic agent without inquiry as to its exact nature and the elements of its entity.

The Relation of the So-called X-Ray Burn to Treatment of Malignant Growths was the title of a paper by Dr. J. Rudis-Jicinsky of Cedar Rapids, Ia. The action of the *x*-rays on the tissues was of marked electrochemical character. Irritation followed, and a regeneration of tissues was the result. Three factors determined the special effect on the cell: (1) Condition of the body, *i. e.* the amount of resistance the rays encounter; (2) The amount and intensity of the rays; (3) The character of the rays. When the irritation was moderate, the cells might be stimulated, but if prolonged, or given in excess, the change might be progressive in the tissues, leading to the so-called burn, regeneration, absorption, reabsorption, or to a total destruction of the cell. The author emphasized the protection of healthy tissues in radiotherapy, and other precautions in each case. He spoke of the selective power of the rays, attacking diseased tissues first. He reported cases, failures, and apparent cures. He discussed the technique and selection of vacuum tubes, according to their burning time; soft tubes or soft medium tubes for superficial growths, and high vacuum tubes for internal growths.

The X-Ray Treatment of Cancer, with Report of Cases Cured.—This was the title of a paper by Dr. Everett J. Brown of Decatur, Ill. The author discussed the subject under the following heads: (1) Technique; comparison of apparatus used; protection of the patient; protection of the operator; the distance of the tube; the time of exposure; the frequency of exposure; and the selection and management of tubes. (2) Description of *x*-ray dermatitis as compared with ordinary burns. (3) The remarkable influence of the *x*-ray on all low-grade tissue was superficial in location. (4) The uncertainty of results in treatment of deep-seated malignant growths. (5) Advantages of the *x*-ray treatment over surgery in many cases: (*a*) painless; (*b*) non-use of anæsthetics; (*c*) less destruction of tissue; (*d*) astonishing results in many cases regarded as incurable surgically. (6) Report of cases cured.

Renal Calculi or Hepatic Calculi: Differential Diagnosis.—Dr. Charles E. Barnett of Fort Wayne, Ind., read this paper. The *x*-ray in differential diagnosis was not as valuable here as in other regions. The author contended that it was impossible to make a differential diagnosis, and suggested cutting down and exposing the kidney, then being governed by the findings.

Cyst of Mesentery.—Dr. Herman E. Pearse of Kansas City, Mo., reported a case of cyst of the mesentery that recovered after operation. He stated that cysts of the mesentery were exceedingly rare.

Through-and-Through Intestinal Suture.—Dr. F. Gregory Connell of Leadville, Col., in a paper on this subject, said that a through-and-through suture should be employed in preference to one that attempted to perforate but a portion of the entire intestinal wall, because of (1) less danger of yielding; (2) less danger of leakage; (3) smaller diaphragm; (4) adhesions were diminished; (5) there was less danger of necrosis; (6) there was no foreign body, and (7) there was a decrease in time. The most appropriate place for the knot of perforating stitches was in the lumen, and as many intentional nonperforating stitches were in reality unintentional perforating stitches, owing to the relative sizes of the needle and the submucosa, it might be stated that the ideal location for the knot in practically all intestinal sutures was outside of the peritoneal cavity in the lumen of the gut. The diaphragm, by its valvelike action, prevented leakage. The square or double stitch was superior to the circular stitch, with its top knot. It was of practical import to have the last stitch, as well as the others, through all of the coats and knotted in the lumen. As the perforating stitch had been substituted for the Lembert by many, it might be said that if twelve Lemberts were bad and ten perforating and two Lemberts were better, then twelve perforating were best. The author closed his paper with a description of the technique, and a report of fifty-four cases.

Gastrojejunostomy with the McGraw Elastic Ligature for the Relief of Gastroptosis.—Dr. H. O. Walker of Detroit, Mich., read a paper with this title. He said that little had been done surgically for the relief of this condition. He reported three cases operated on successfully, and closed by saying that of all methods that had been suggested for the performance of lateral intestinal anastomosis, none, to his mind, possessed the advantages of the McGraw elastic ligature: (1) Its simplicity was far greater than any other method yet presented; (2) The ease and rapidity with which it could be done; (3) Less liability to sepsis than by any other method; (4) There was no danger of a foreign body; (5) A larger opening could be made without liability to cicatricial contraction. Dr. Walker exhibited beautiful charts showing the steps of the operation.

Section Following Vaginal Puncture.—Dr. John Young Brown of St. Louis, Mo., read this paper, in which he spoke of the value of vaginal section in selected cases of pus in the pelvis. He called attention to vaginal section in contradistinction to so-called vaginal puncture. He alluded to the post-operative complications following vaginal section, as shown by a series of cases in which abdominal section was subsequently done.

Cancer of the Uterus in the Mississippi Valley was the title of a paper read by Dr. Emory Lanphear of St. Louis, Mo. The author said that Eastern surgeons did not operate on cancer of the uterus, while Western surgeons did. What was the result? The census statistics of 1900 showed cancer of the breast, on which all operated, East and West; cancer of the stomach, on which no one operated, and cancer of the uterus, as follows: East, cancer of the breast, 613 cases; cancer of the stomach, 1,785 cases; cancer of the uterus, 1,101 cases. Mississippi Valley, cancer of the breast, 874 cases; cancer of the stomach, 3,776 cases, and cancer of the uterus, 679 cases. The difference showed larger proportions of carcinoma uteri operated upon in the West, with either a cure or return of the disease in other organs; hence death was not included in the deaths from cancer of the uterus. Reports from seventy-four operators in the Mississippi Valley showed 274 cases which had lived more than five years. The diagnosis was confirmed by the microscope in most cases, a result encouraging for earlier diagnosis and prompter hysterectomy.

A Plea for the Abandonment of the Abdominal Belt After Cœliotomy.—Dr. Maurice Kahn of Leadville, Col., read a paper on this subject. It was the writer's belief that if, in consequence of his plea, sufficient interest was aroused in the subject, it would be but a short time when the post-operative abdominal belt would be obsolete. Attention was called to the direction of the muscular fibers, which intersected each other at angles varying from about 25 to 90 degrees. By reason of a common nerve supply, the abdominal muscles acted synchronously. The excellent cancellated arrangement of the abdominal muscle fibers made the gridiron operation the one of choice, for then the contraction of the muscles tended in itself to safeguard against hernia. He believed the straight through technique to be the most effective factor in subverting an ideal result in most cases, not so much because the muscles were cut transversely, but because of inaccurate suturing. The application of an abdominal belt, which, if tight enough to exert any influence, must relieve the muscles of their usual labor, resulting in the atrophy of non-use, whereas it would be desirable to have the hypertrophy of over-use. If it were possible to apply a belt internal to the abdominal wall, it might, perhaps, be of service in giving the cut edges an opportunity to firmly unite before any strain was imposed upon them. Such arguments could not be advanced in favor of the external abdominal belt, which would not prevent the exertion of pressure on structures internal to itself. It had been his practice for over three years, after removing the first dressing, which was applied snugly for comfort, and removed at the end of a fortnight, to allow patients to go without any support.

Early Diagnosis and Conservative Treatment of Fibromyomatous Tumors of the Uterus.—Dr. L. G. Bowers of Richmond, Ind., called special attention to the importance of the early diagnosis of fibroids, thus leading to conservative methods of treatment. He enumerated some of the symptoms of fibroids that were many times attributed to other trivial causes by a superficial examination, and insisted that the patient be examined under an anæsthetic and curetted at the same time, if necessary. He pointed out that most of the literature dealt exclusively with the operative views, and nothing was said about preventive measures. The early practice of such treatment often obviated the necessity for hysterectomy later on.

Treatment of Fractures of the Patella.—Dr. David C. Peyton of Jeffersonville, Ind., discussed the relative frequency of these fractures, the contractions of the quadriceps as an efficient agent in the etiology; the displacement of the fragments, and the associated injuries to the soft parts; the diagnosis, and then outlined the advantages of treatment by open arthrotomy as compared with non-operative procedures.

Dr. Truman W. Brophy of Chicago gave a lantern demonstration of his method of operating on cases of cleft palate. He also exhibited patients upon whom he had operated, showing excellent results. The patients were able to articulate remarkably well.

Dr. C. E. Ruth of Keokuk, Ia., discussed the subject of anti-streptococcic serum in septic conditions.

A resolution was adopted making the Mississippi Valley Medical Association a district branch of the American Medical Association. The constitution and by-laws of the former will be revised to conform to this change.

The following officers were elected: *President*, Dr. Edwin Walker, Evansville, Ind.; *Vice-Presidents*, Dr. Hugh T. Patrick, Chicago, Ill., and Dr. Wm. Britt Burns, Memphis, Tenn.; *Secretary*, Dr. Henry E. Tuley, Louisville, Ky.; *Treasurer*, Dr. Thomas Hunt Stucky, Louisville, Ky.

Memphis, Tenn., was selected as the place for holding the next meeting, in 1903.

The Differentiation of Diphtheria and Pseudodiphtheria Bacilli.—Bronstein and Grünblatt have endeavored to simplify the complicated method of Neisser for determining the reactions of the culture medium in differentiating the true and false diphtheria bacillus. Neisser's method requires a series of titrations which consume time and are too troublesome for routine work, and the authors propose to use Mankowski's fluid as a substitute. This is prepared as follows: A. 2.0 g. of indigo-carmine are dissolved in 100.0 c.c. of distilled water, and B. 10.0 g. of acid fuchsin in 100.0 c.c. of 1 per cent KOH solution. The solution for use is prepared by taking 2 parts of solution A, 1 part of solution B, and 22 parts of distilled water. This fluid is very sensitive to changes of reaction, and becomes red in the presence of acid and green in the presence of alkali. The broth to be used must be rendered neutral by using the fluid itself as indicator, and should, furthermore, be as fresh as possible. The test is made by sowing the pure cultures in question in tubes containing about 5 c.c. of bouillon, prepared as indicated, and kept in the thermostat for twenty-four hours, together with a control tube of clear broth. At the end of this time three drops of the reagent are added to each tube. Normal broth immediately becomes blue, cultures of the Loeffler bacillus ruby red, and pseudodiphtheria cultures green, the latter color appearing only after several minutes.—*Centralblatt fur Bakteriologie, Parasitenkunde, und Infektionskrankheiten.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 1, 1902.

	Cases.	Deaths.
Measles	60	1
Diphtheria and croup	326	26
Scarlet fever	129	7
Smallpox	1	1
Varicella	31	
Tuberculosis	229	136
Typhoid fever	126	31
Cerebrospinal meningitis	..	7

Increase of Insanity in London.—I learn from the annual report of the Asylums Committee of the London County Council that the increase of lunacy in London last year was greater than it has been in any year since 1896. On January 1 last the number of London lunatics under the cognizance of the Asylums Committee had reached the appalling total of 22,155. A new asylum was opened in March last for the accommodation of 2,000 patients, and already the committee has under consideration the necessity of proceeding with the construction of another building, in order to provide for the estimated increase of 500 cases per annum. At this rate the burden of providing for over half a million lunatics will be imposed, by the end of the century, upon the unfortunate inhabitants of London who manage to retain their sanity.

Among the causes of insanity in patients admitted hereditary predisposition is held accountable for 27 per cent. of the cases and alcoholic intemperence for 17 per cent. If it were possible, however, to investigate fully the family history of every patient, it is quite likely that alcohol might be proved to play an even more prominent part in the causation of insanity than these figures indicate.

Bearing on this question, a most interesting history of a family of inebriates appeared recently in the *Quarterly Journal of Inebriety*, accompanied by a genealogical table for four generations. The first generation comprised a married couple of good social position, who apparently did nothing to forfeit their reputation. They had two daughters, one of whom died a raving maniac at forty after a life of the wildest excess. The second married and had eight children. Of this third generation, two males are drunkards and alive, five daughters died of phthisis, the sixth married, and after bringing seventeen children into the world became a drunkard and opium eater. Ten of these seventeen, comprising the fourth generation, have died from phthisis, one has drifted into a life of immorality, one suffers from phthisis, one died from an overdose of morphia taken when drunk, one committed suicide and three suffer from suicidal mania in varying degrees. No wonder that asylums are full and the death rate from phthisis steadily increases.—*London Truth.*

The Second Report of the British Royal Commission on Sewage.—This volume consists entirely of a valuable series of reports dealing with various points, such as the methods best adapted for use in the examination of sewage and effluents, the standards which should be adopted, and the result on pathogenic organisms of various methods of treatment. These researches have been undertaken by Professor Boyce, Drs Houston, MacConkey, McGowan, Grunbaum, and Hill and Mr. C. Frye. Dr. Houston requires that before an effluent be discharged into a stream, the water of which is used for drinking purposes, there should be an absence of putrescible matter as judged by chemical tests, and freedom from the germs of epidemic disease, as judged by the absence of the B coli from 1 c.c. of the sample. From these researches it appears possible for pathogenic organisms to resist destruction by other organisms. The B. typhi abdominalis was unable to multiply in crude sewage or sewage effluents, and disappeared within seventeen days at the most, but the B. anthracis was found five months after the sewage installation had ceased working. Effluents from bacteria beds attain a high standard of chemical purity, but these observers state that bacteriological examination will reveal the presence of countless numbers of B. coli and other saprophytic inhabitants of the intestinal canal. If this is to be regarded as the source of such organisms, then it is evident that more is necessary for the purification of such effluents, but, in the nature of things, these researches, valuable as they are, must not be regarded as in any way final, but rather as "strivings for the light."—*Public Health.*

Botryomycosis in Man.—This disease, described by Poncet and Dor, in the human subject, has been believed to be occasioned by a special parasite, regarded also as the cause of the fungating growths which succeed castration in the horse. Clinically, it appears in the form of a bud or berry—like masses, more or less ulcerated, attached to the skin by a small pedicle. The growths themselves are soft, indolent, and elastic, with a rough and villous surface, and a red color. They are met with particularly on the hands of farm laborers and grooms. As their nature and causation has been disputed, Bodin—Ann. de dermat. et de syph., Paris, April, 1902—has investigated into two typical examples. The pedicle is composed of strands of connective tissue, enclosed within an epidermic wall. The body of the neoplasm consists of small, young, connective tissue, rich in blood vessels, with delicate boundary. In the center are a few mast cells and leucocytes with polymorphous nuclei, as the surface is approached, embryonic cells infiltrate the tissue to a greater extent, while the periphery is found of necrosed cells, aggregated into a crust. From both sides identical microbes were isolated and cultivated side by side, with a yellow staphylococcus taken from a pustule of impetigo, and another from an osteomyelitis. A comparative study brought out the same characters, objective and biological, as the staphylococcus aureus. He concludes that the so-called muriform masses of botryomyces are but yellow staphylococci, and botryomycosis of man is only a rank granulation, due to this microbe, and taking the peculiar form from exigencies of situation.—*Edinburgh Medical Journal.*

French Infant Mortality—M. Gaston Leroux publishes in the *Matin*, says the *Scientific American* supplement, an article on the infant mortality caused by bad and adulterated milk. He quotes statistics of a most painful nature which would seem to demonstrate beyond doubt that an enormous percentage of the children who die annually in France are literally poisoned by bad milk. This article is illustrated by a map of France, on which the greater or lesser mortality from that cause is indicated by a small or large black spot. A glance at it shows that France may be divided into two regions, one on the north of the Loire, where more than half the children that die succumb to gastritis, whereas to the south of the Loire not more than one-third die from that disease. At Troyes the percentage of the infants carried off by gastric diseases is 69; at Mans, 63; at Rennes, 64; at Boulogne-sur-Mer, 49; at Amiens, 62; at Lille, 56; at Paris, 36. In the south of France the comparatively few deaths of infants from that disease is most striking. At Toulouse it is 31 per cent. of the total infantile mortality, at Beziers, 12 per cent., and at Clermont only 6 per cent. Explaining the phenomenon of the high rate of infant mortality from gastritis to the north of the Loire compared to that in the south of France, M. Gaston Leroux says it is due to the adulteration in the north of the country, where the making of butter is a great industry, whereas very little butter is made in the south. He considers that it is, moreover, now completely established that to feed certain children even on unadulterated milk which has been skimmed of all the cream is a dangerous and guilty practice.

Monetary Cost of Consumption.—It is calculated, says the *Medical Press*, that there is spent in the United Kingdom upward of £1,000,000 sterling ($5,000,000) every year, through the poor rates alone, on the victims of pulmonary tuberculosis. Moreover, of the 42,000 who die annually of this disease, the majority are between twenty and forty years of age—that is to say, they are lost to society just when they are in a position to make good the cost of their maintenance and education. The mere loss in wage-earning power is estimated at from ten to twelve million pounds ($50,000,000 to $60,000,000) annually. It follows that any means, however costly to begin with, which will have for effect to reduce materially this prodigious waste of life and working energy, ought, in the end, to prove a remunerative outlay to the community.

A Cave Sanatorium.—The *Scientific American* says: "It has been discovered that the air from limestone caves has all the characteristics of the mountains. This discovery has just been made use of in the location of a sanatorium near one of these caves, and the air for the institution is supplied from the underground caverns. This establishment is at Luray, Va., and the system of ventilation is arranged so that each room gets its own supply direct from the cave. The air of these caverns is of a uniform temperature, and remarkably pure and free from all germs and dust particles. In the warmest weather the doors and windows of this institution are kept closed, and a comfortable temperature of 75° is maintained in spite of one of 90° or more encountered outside.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending November 1, 1902:

THE PRIMARY NEW GROWTHS OF THE PLEURA.

By FRANCIS DELAFIELD, M.D.,
NEW YORK.

THE bibliography of endothelioma of the pleura is given by Gloekner, *Zeitschrift der Heilkunde*, XVIII, p. 209. The number of cases of primary tumor of the pleura so far reported is small, so that I think it is worth while to report four cases which have been under my own observation.

It is generally agreed that these tumors are endothelial growths, which originate in the lymphatics of the pleura. There is a new growth of cells from the endothelium of the lymphatics, and an increase in the size and number of the lymphatics. At the same time the pleura itself is split up by an extensive new growth of cells, and there is a large transudation of blood serum rich in fibrinoplastic substances. In the earlier stages of the growth there are no tumors, only a diffuse thickening of the pleura, and, imbedded in this, tubules lined or filled with endothelial cells. Later, tumors are formed of different sizes, projecting inward, composed of a basement substance containing tubules, or irregular cavities filled with polygonal cells. The pleura is coated with fibrin, and large quantities of serum collect in the pleural cavity. The inflammatory changes in the pleura are so marked that they may easily mask the new growth. In its earlier stages the real character of the lesion may be overlooked. The new growth and the inflammatory changes may be confined to one pleura, they may involve both pleuræ, or the peritoneum also may be affected in the same way. The history is that of a pleurisy with effusion, which is unusually severe, and which terminates fatally.

During the first weeks it is hardly possible to distinguish these cases from ordinary cases of pleurisy with effusion. The story of the invasion, the behavior of the patient, and the physical signs, are all the same. Only the bloody serum and the low temperatures are suspicious. But, as the weeks follow each other, the loss of flesh and strength, and the appearance of the patient make one think more and more of malignant disease.

CASE I.—Primary endothelioma of the pleura. Female, fifty-three years old, September 15, 1880. Four weeks ago she caught cold. Since that time she has had a cough with scanty expectoration, has been chilly and feverish with dyspnœa, pain and oppression on the right side, and loss of flesh and strength. She is now feeble and emaciated, with a little cough, dyspnœa and pain and oppression over the right chest, pulse 100, breathing 24, temperature 98° F., urine 1024, no albumen or casts. The physical signs are those of fluid in the left pleural cavity.

September 18. Fifty-five ounces of clear serum were aspirated from the left pleural cavity, temperature 99° F.

October 12. The woman feels better and is out of bed.

November 19. A quantity of dark-brown, slightly purulent fluid was aspirated from the left chest.

December 14. The chest was again aspirated and the same dark-brown fluid drawn off.

December 21. She died rather suddenly.

Autopsy.—The brain was not examined. The heart was normal; it was displaced to the right of the sternum. The right lung was normal. The left pleural cavity was nearly full of bloody, purulent serum. The lung was compressed against the vertebral column. The pleura was thickly coated with fibrin. Vertical sections of the costal pleura showed on the inner side, a layer of fibrin and pus. Beneath this was a layer of reticulated connective tissue. In this were tubules filled with large, polygonal nucleated cells. Beneath this layer was the pleura itself its cells increased in size and number. In flat sections the tubules looked like lymphatics. The liver and spleen were normal. The kidneys were of medium size, their capsules adherent, and their surfaces finely nodular.

CASE II.—Primary endothelioma of the pleura. Male, sixty-three years old, June 12, 1883. Two weeks ago he caught cold, and had cough and pain in the right side of the chest. He came into the hospital with these symptoms, and with a friction sound over the lower lobe of the right lung. He remained in the hospital until June 16, and was then discharged improved. He was readmitted July 25. The pain in the right side has continued, and he has had to stop work. There is flatness on percussion, with absence of voice and breathing, on the right side of the chest from the angle of the scapula down.

September 15. A little bloody serum was aspirated from the right chest.

October 3. Thirty-seven ounces of bloody serum were aspirated from the right chest. After this the man steadily lost flesh and strength until October 8, when he died.

Autopsy.—The brain was not examined. The heart was normal. The left lung was emphysematous. The right lung was confined by old adhesions to the upper third of the thorax, the lower lobe was compressed. The lower part of the pleural cavity was full of bloody serum. The costal, pulmonary, and diaphragmatic pleura were coated with fibrin, thickened and studded with small and large white nodules. The nodules are composed of a connective tissue stroma, enclosing irregular cavities filled with flat nucleated cells. The liver was fatty. The stomach, intestines, and spleen were normal. The kidneys showed the changes of chronic nephritis with commencing atrophy.

CASE III.—Primary endothelioma of the pleura. Male, sixty years old. November 27, 1884. The man says that he was at work until six weeks ago. Then he began to have pain on both sides of the chest; dyspnœa on exertion, cough with mucopurulent and bloody sputum, and occasional vomiting. Now he is feeble, emaciated, stupid; pulse 94, breathing 18, temperature 98°. There is flatness and absence of breathing over the whole right lung behind. The man lay quietly in bed, growing more feeble and emaciated every day, until December 11, when he died.

Autopsy.—The left pleural cavity contained a little serum. The left lung was coated with old adhesions, and there were small, white, flat nodules in the pulmonary pleura. The right pleural cavity was distended with bloody serum. The lung was compressed against the vertebral column. The costal and diaphragmatic pleura were thickly studded with large and small white nodules. The growth in the pleura was composed of polygonal cells, arranged in tubules. The pleura was split up and filled with connective tissue cells. There were very marked changes in the endothelium of the costal pleura. The cells looked like cylindrical cells, and were in masses. The heart was small; the aortic and mitral valves were calcified. The liver had old adhesions over its entire surface. It contained several large white nodules, some of them continuous with nodules in the diaphragm. The spleen was large and firm; it contained a large white nodule. The peritoneal cavity contained bloody serum. There were nodules of new growth in the omentum and the mesentery. The stomach was small and congested. The intestines were normal. The kidneys were normal.

Case IV.—Primary endothelioma of the pleura. Male, forty-five years old, June 6, 1884. Three weeks ago he began to lose appetite and feel weak. One week later he had dyspnœa on exertion, slight cough, with mucous expectoration and pain in the chest.

June 6. There is flatness on percussion, and absence of voice and breathing over nearly the whole of the right chest.

June 15. Nineteen ounces of bloody serum were drawn off from the right pleural cavity. His temperature has ranged from 98° to 100° F.

June 17. He died suddenly.

Autopsy.—The brain was not examined. The heart was normal. The right lung was compressed against the vertebral column. The pleural cavity was distended with bloody serum. The costal and diaphragmatic pleura was irregularly thickened, and there were small white nodules in the costal and pulmonary pleura. The left pleural cavity was half full of bloody serum. The costal pleura was thickened and congested, there were small white nodules in the pulmonary pleura. The costal pleura of the right side was thickened and converted into granulation tissue with numerous blood vessels. In the deep layers of the pleura were small cavities filled with nucleated polygonal cells, in other places the cavities were larger, and occupied most of the thickness of the pleura. The liver, spleen, and kidneys were normal. The peritoneal cavity contained turbid serum, and the peritoneum was thickly studded with small white nodules. The intestines were normal.

Union Mission Hospital of Philadelphia.—The contract has been awarded for the erection of a large addition to this hospital, to consist of a three-story and basement building of fireproof construction, with exterior walls of brick and stone. The dimensions will be 60.9 by 93 feet. In the basement will be located the laboratory, the *x*-ray room, a fan-room, steward's quarters, a mortuary, toilet, and laundry, trunk and store rooms. The first floor will be given up to the general offices, the pharmacy and clinics. On the second floor will be private rooms and wards. The third floor will have rooms for private patients and wards, a dining room, a kitchen and nurses' quarters. The cost of the new structure, exclusive of equipment, will be $50,000.

THE PRESENT STATUS OF RADIOTHERAPY IN CUTANEOUS DISEASES AND CANCER.

By CHARLES WARRENNE ALLEN, M.D.,

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POST-GRADUATE SCHOOL.

A sufficient time to permit of certain positive deductions has now elapsed since the possibility of curing hitherto almost incurable affections by means of the Röntgen ray came to us as a surprise and a pleasing hope. In a paper which I have just read before the New York State Medical Association, I have reported fifty personal cases of cancer treated during the year, with results which are, to say the least, encouraging. In age, the patients ranged from fifteen to eighty years, thirty being over fifty years of age. Twenty-two were male and twenty-eight female. As to the nature of the cancerous process, the majority, or thirty-three, were epithelioma of the rodent ulcer type, or occurred as firm nodular or warty growths, or as cutaneous carcinoma. There were ten instances of mammary cancer, seven being recurrent and three primary; one was a primary rectal cancer; one was a tumor of the jaw supposed to be sarcoma; one was cancer of the tissues of the neck, following cancer of the tongue; three were sarcoma, and one was recurrent uterine cancer. Although in this series of cases certain adjuvant treatment was employed in some, though not in all, the results were such, in regard to duration of treatment, final outcome, nature of resulting cicatrix, etc., as to leave no doubt that the ray had been of unquestionable benefit. The results may be briefly stated as follows:

	CASES	PER CENT.
Ending fatally	5	10
Discharged as unimproved, or ceased treatment unimproved	3	6
Referred for surgical operation	2	4
Ceased treatment improved	4	8
Improved and still under treatment	10	20
Discharged as clinically cured	26	52
	50	100

Although there were five deaths, it is only fair to mention that eleven of the cases were as hopeless from the beginning of treatment as all who have had experience know that recurrent breast and uterine cases, cancer of rectum, recurrent cancer after cancer of tongue, and pigmented disseminated sarcoma may be. Although there has been included in this series a case of pigmented sarcoma which practically had no *x*-ray treatment, but, against the writer's advice, underwent a surgical operation, still it has been included, since the series is a consecutive one, showing results, good, bad, or indifferent, for all cases coming under treatment. As to the nature of this new therapeutic force, it is pretty clear that the action of the ray is a reducing one, and that the resistance of tissues to its effect is inversely proportionate to their degree of vitality. Thus certain portions of the hair, nails, and most neoplasms of a mucoid or embryonic-like structure, will be caused to disintegrate much more readily than will adjacent healthy structures, or those more highly vitalized.

It is generally accepted that the rays from a low tube—that is, rays which are absorbed by the surface tissues—produce more reaction effect, or result in the so-called burn, or dermatitis, than those from a high, or penetrating, tube, whose rays pass more readily through the tissues. Aside from this, I have noticed a distinct tendency in tubes at times to produce these effects, it has seemed to me, irrespective of their condition of vacuum, or of any idiosyncrasy on the part of the patient. There is no doubt a difference in susceptibility of different individuals, but this is by no means the only factor. The effect of the ray treatment in deep-seated. extensive cancers is at times to cause so great and rapid a disintegration of tissue that the system is overloaded with waste products, and great stress must be laid upon the necessity of constantly watching and controlling the hygienic and general constitutional condition of such patient, and for this reason the treatment should be applied or constantly supervised by the skilled physician, and not entrusted to the electrician.

Several theories are at present extant as to the nature of the ray, the most probable being that, at the point of impact of the cathode stream, there is sent into space in every direction a multitude of molecules, negatively electrified, traveling in straight lines, and at an enormous velocity.

The statement has been made that primary breast cancer should not be subjected to the ray treatment, but that first a surgical operation should be done. The gentlemen who uphold this view lose sight of the important fact that a very large class of patients rejected surgical measures before the ray treatment was thought of. There exist to-day thousands of primary cancers, well advanced, which will never come under the surgeon's knife—ray or no ray. To this large class the new treatment offers much hope. Perhaps the most gratifying case of my series is one of this nature, in which cutting had been absolutely rejected by a most intelligent lady, who had studied the subject for herself before radiotherapy was suggested. Although the growth was very extensive, and the patient's condition critical when the treatment was begun, in January last, there has been steady, though naturally slow, improvement. An open, flat, ulcerating surface, and gradually decreasing in extent, presenting day by day less evidence of malignancy, has taken the place of an extensive cancerous mass, the offensive and abundant secretions of which were draining the patient's vitality, and the occasional hemorrhage from which was jeopardizing life. Here the ray has without doubt proven a boon, for which we have to-day no known substitute.

In several other breast cases there has been local improvement which was, for a time, most encouraging, and one patient was cured of the recurrence in the skin tissues involving and adjacent to the scar of operation, as well as of lesions more widely disseminated over the trunk. Here, however, there was suspicion of subsequent internal metastasis, and I believe the patient succumbed to intercurrent pneumonia.

I have applied the ray during the past year to a great variety of skin affections, including a number of cases of lupus, lupus erythematosus, inveterate psoriasis, obstinate eczema, acne, sycosis, leprosy, xeroderma pigmentosum, favus, ringworm, lichen planus, etc. On the whole, I can report in a general way that the ray is of decided aid in combating these rebellious affections, and although I do not rely upon it solely, any more than I do in external cancer, I have secured in many cases better and quicker results than by the older methods alone. In such affections as Hodgkin's disease, internal sarcoma, and cancer of the liver, which I have treated at the kind suggestion of some of my colleagues, I have naturally relied upon the rays alone, and, although I have no cure to report, I can announce some gratifying improvements.

30 East Thirty-third Street.

BIOGENESIS AND HEREDITY.*

A DISCUSSION OF THEORIES AND THE ADVANCEMENT OF A MODIFICATION OF THE CHEMICAL THEORY WITH APPLICATIONS.

By RAYMOND WALLACE, M.D., M.S.,
CHATTANOOGA, TENN.

The presentation of a subject along the line of pure science, and verging, perhaps, upon the philosophical, may be justified by the continual broadening of the medical horizon, which leads us from the narrow confines of symptoms and treatment to a more detailed consideration of etiology and prophylaxis along the lines of sociologic and biologic investigation.

Recent work has aroused considerable enthusiasm and interest in the cause and nature of the vital phenomenon and its relation, biologically, to the problem of heredity. With the enunciation of the cell-theory in 1838–39 by Schleiden and Schwann, with the development of embryology upon that theory as worked out by Kölliker and Remak, and with the correlation of these facts to the functions of the body as involved in health and disease, at the hands of Max Schultze and Virchow, the problems of biogenesis and heredity have been brought to light, and recent years have yielded considerable advancement through the investigations of Hertwig, His, Van Beneden, Strassburger, Loeb, and a host of others.

It is a theory which was proposed by Ehrlich in connection with his work on Immunity, and which was last year set forth more definitely in a paper by Professor Adami of McGill University, that I desire to discuss here, and, perhaps, I may advance a further modification of that theory.

Since earliest times there have been hypotheses, more or less fantastic, to account for the origin of life, and for the resemblances and variations manifested in successive generations of the same species. But the fantastic has now almost completely given way to the physical and metaphysical, the materialistic and the spiritualistic. The theories, however, are still largely speculative, and no one of them can claim to be preeminently accepted by the workers on the subject.

Positivistic monism was the dominant note of nineteenth-century speculations. It erred, however, in that it tried to make science purely utilitarian depriving the human mind of all metaphysical capacity; but experience, joined with speculation, has undoubtedly been the indispensable basis of all positive knowledge, and almost the entire scope of scientific research has been compelled to pass through the vale of metaphysics. Though the problems of heredity and biogenesis can hardly hope to pass completely out of this realm, any more than has the absolute establishment of the atomic theory, yet a theory of biogenesis may be evolved which shall lay surer foundations for a comprehensive science that will yield more of value and significance to the world than either chemistry or physics. Speculation, then, in its ultimate results can yield nothing but good.

Materialistic monism, as fathered by Darwin, denies all purposiveness—all finality. Idealistic monism recognized in Nature, if not the designs of a Creator, at least an immanent finality. The primary principle preceding physical organization, philosophers for ages have discussed, and in recent decades, biologists have theorized and experimented upon. Thus Hegel's "Creative Idea" was not conscious intelligence, but a principle which, when provided with a cerebrum, becomes conscious. Materialism reenforced by the descendants of Hegelianism placed the transformistic theory of Lamarck and Darwin against the miracle of creation; it advanced chemical synthesis against the fantasy of a "vital principle," the theory of the equivalence and transformation of forces and electricity against the hypothesis of a separate force to explain thought.

---

*Read before the Tri-State Medical Society of Alabama, Georgia, and Tennessee, October 7, 1902.

The purpose of this paper is to point out in detail some of the biological and cytological evidence for the necessary assumption of an idealistic monism with its immanency or primitive principle which preceded physical organization, and to determine what of positive and what of theoretical bearing can be elicited, sympathizing with Weissmann's apology that "Hypotheses, even when not absolutely right, may be of value in advancing our knowledge, if only they are relatively right; that is, when they correspond with the states of existing knowledge."

Various theories, more or less speculative, have been advanced, and a very brief review may at this point be of some advantage.

The theory of preformation postulated that the germ-cell contains a veritable miniature of the future organism, the development of which consists in a process of unfolding and evolution.

In the idioplasm theory Naegli theorizes that heredity is not transmitted by the cell as a whole, but by a particular part, the idioplasm of the nucleus, and that the trophoplasm is an indifferent substance. Thus he suggests that hereditary traits are the outcome of a definite molecular organization of the idioplasm, and subsequent work has identified this idioplasm with the chromatin of the nucleus.

Spencer suggested that the germplasm consists of a collection of "minute elementary vital particles"—a theory somewhat analogous to Darwin's theory of pangenesis, in which he assumes that the somatic cells throw off minute granules, which are dispersed throughout the system, and that they are collected and constitute the sexual elements, which, when supplied with proper nourishment, multiply by cell-division, and are ultimately developed into units like those from which they were originally derived.

The theory of germinal localization, as advanced by His, conjectures not that the embyro is performed, but that it is predetermined, as a function of the geometrical location of the various molecular groups.

The most interesting of these theories is the one advanced by Ehrlich and recently accentuated by Adami of McGill University. They venture a chemical theory which makes living organisms naught but chemical machines, all growth and differentiation being determined by definite chemical change. It is postulated that the idioplasm of the nucleus consists of a mass of material, each molecule of which is composed of a central indestructible carbon or cyanogen ring, which, perhaps, determines the nature or function of that particular cell, to which various molecular or atomic side-chains can become attached or detached without impairing the integrity of the central ring. Thus the molecule is conceived as consisting of an immutable central ring, with numerous unsatisfied valences, which becomes satisfied and depleted in the accomplishment of the various life processes.

Adami further states that only cells which are undifferentiated, or cells which have lost their differentiation, are found to undergo division. Primitive idioplasm must, then, be essentially a simple molecular substance, and becomes differentiated only as a reaction to certain stimuli by the taking on of side chains. Thus reducing undifferentiated cell life to such a molecular simplicity, it is reasoned that the life phenomenon itself is naught but a chemical state of the constituent molecules of the cell.

Pflüger (*Archiv für die gesammte Physiologie*, 1875, Bd. 10, p. 251) calls attention to the great instability of living matter, and postulates that living matter is composed of very complex and unstable molecules which are continually being disassociated into more stable compounds, such as H_2O, CO_2, and urea; that is, the intramolecular movement of the cell is its life.

Loeb theorizes along the same line, that the difference between living and dead matter is that in the former we have a very unstable or labile molecule in which the atoms are in active motion, which instability he explains as due to certain groupings of the atoms. Dr. George Adam, at a recent meeting in San Francisco, has presented a most fascinating article on the relation of ether to the physiologic unit. It corresponds somewhat to the work of A. T. Matthews, as described in the *Century* of March, 1902.

Dr. Adam concludes that the physiological actions of nerve, muscle, gland, etc., are initiated by chemical potentials, that the stimulus is electrical only in so much as chemical and electrical potentials are fundamentally identical. The chemical stimulus, he says, does not involve an interchange between the stimulating and stimulated molecules or cells, but a polar attraction without reciprocal dissociation. He concludes that a "molecule, whether belonging to an organic or inorganic substance, in a condition of rest, or in solution, or in an unpolarized solid condition, is in the electric state, without poles, and having a uniform magnetic field, and when functionating, or in a polarized condition, is in the magnetic state, with differentiated induced fields. Thus induced electrification, magnetization, crystallization, coagulation, contractility, conductivity, gland-cell action, and numerous other physical and physiologic phenomena have a common fundamental principle."

Now, so far as has ever been demonstrated, the molecular composition of a living cell and of that same cell dead is the same—although the living cell possesses numerous qualities of assimilation, secretion, growth, and reproduction that the dead cell does not. There is then, manifestly, something in the molecular mass, the idioplasm of the cell nucleus, which is peculiar to it and which differentiates it from all non-living matter. There may be a change from a lability to a stability of the molecules in the death process, there may be a de-ionization, or there may be a disappearance of polarity. Apply a theory of causation here. Assume with Adami the presence of immutable rings with numerous transient side chains. This is, however, equally true of what we call inanimate matter, such as wood, stone, and the like. We assume a molecular and atomic structure of these inorganic substances, and these molecules are held together by a force which we designate as cohesion or affinity. There are certain intramolecular activities or forces, the results of which we see in processes such as crystallization, coagulation, magnetization, etc. Some investigators make the statement that, having the processes of assimilation and contractility, it is possible for the act of cell-division to be traced to purely physical and chemical laws.

But molecules composing organic cellular matter have a power of self-division and multiplication—in fine, the property of life—which all other matter has not. These cells multiply. Whence the stimulus which causes this phenomena. If life is not an inherent property, why does not inorganic matter, subjected to every conceivable force of nature, spring to life on every hand? It is explained by Loeb and others by the lability or stability of the constituent molecules. But what gives origin to this lability that is life? Or if life be a phase of electrical phenomena, what occasions the polarization—the magnetic state, with differentiated poles and differentiated induced fields?

It would seem that a primitive force or principle must first place the molecules in a vital constituency, and then, held there by that force, the various chemical and electrical activities may accomplish the processes of the living organism.

The effort to identify this force with other known forces must eventually prove futile, for it is a distinct entity. Certain properties, such as irritability and contractility, which are common to both organic and inorganic matter, have been produced artificially, but the essential attribute of living matter, reproduction, has not been assailed, and for the reason that it involves a primitive principle, a force which is in itself immanent—inherent in living matter. Having once established the vital constituency, under its influence the other forces of chemistry and physics then play their part.

Certain salt solutions may cause unicellular organisms to undergo cell-division; misplaced germinal cells may undergo a seemingly spontaneous development, and thereby give rise to a teratoma; normal tissues of the body may, through the influences of germs, toxins, or irritation become malignant, but the hope of bringing certain chemical compounds into a definite relationship—and flash! and there is life—would seem, from our present sound knowledge, to be wildly extravagant. *Omne vivum ex vivo.*

The idea of biogenesis having been discussed, let us now briefly consider the nature of *cell-growth* and *cell-division.*

Having a mass of molecules, which have been grouped into a vital constituency by this primitive force, and held there by it until the death phenomenon, the cell assumes numerous functions, most of which can be interpreted under known forces, from the realms of chemistry and physics: thus reverting to Adami's chemical theory—the processes of assimilation, nutrition, and, consequently, growth, secretion, motility, irritability, and conductivity are happily and rather simply explained. Indeed, the stimuli to cell-division and the process itself may be entirely mechanical, but the force which holds the mechanical elements in the vital constituency is primitive and immanent.

Such a theory does not stifle inquiry, as one might at first suppose, by inferring that the "primitive force" is ultimate, and, therefore, experiment is vain. On the contrary, this theory simply separates the force which establishes the vital constituency from the realm of chemistry or physics, and, calling it an entity, welcomes investigations and inquiry as to its nature.

This force may be analogous to chemical affinity or other known forces, or, in turn, it may be phases of it, but it must appear, from present knowledge, that it is a complete entity, the nature of which we still seek to know.

The field which it was originally intended this paper should cover has so gradually widened, as various phases of the general subject have come into thought, that the minute consideration has, perhaps, become a little more superficial and less detailed. However, the subject of biogenesis, involving as it does the basic problems of biology and philosophy, which have been argued since the ages began, can admit, from the present attitude of science, of but a transitory and almost entirely theoretical treatment.

Yet if, by the rehearsal of well-known facts and the re-statement of old theories, any new ray of light has been flashed into the great chasm of darkness which still holds the basic problems of life, this thesis shall not have been in vain. And it cannot be denied that the purpose of this paper has been primarily an endeavor to redeem the problems of the life phenomenon from the attempted complete explanation in the realm of pure chemistry and physics, by adducing definite cytological and biological evidence that, antecedent to the appearance of chemical activities in living protoplasm, there must exist a primitive principle which places matter in a life constituency, interpreting that principle as you will.

It is to me most significant that Wilson in his great work on "The Cell in Development and Inheritance" concludes with the admission "that the study of the cell has, on the whole, seemed to widen rather than narrow the enormous gap that separates even the lowest forms of life from the inorganic world," and Darwin, at the close of his great masterpiece, "The Origin or Species," bursts out with this pregnant declaration: "There is a grandeur in this view of life, with its several powers, having been originally breathed by the Creator into a few forms or into one; and that, while this planet has gone circling on, according to the fixed law of gravity, from so simple a beginning endless forms, most beautiful and most wonderful, have been, and are being, evolved."

THE CRIMINAL RESPONSIBILITY OF THE EPILEPTIC.*

By JOHN PUNTON, M.D.
KANSAS CITY, MO.
EDITOR OF THE "INDEX LANCET," ETC.

The intricate problems associated with epilepsy appeal at times to both law and medicine for their intelligent solution. By virtue of its extreme antiquity and vital importance to the well-being of all classes of society, epilepsy also challenges the interest and attention of every loyal citizen. Long before the Christian era it was recognized as the Herculean disease, not simply because Hercules was subject to epileptic attacks, but on account, as Galen says, of its extreme severity and magnitude. Notwithstanding the fact that Hippocrates described its purely objective physical phenomena with characteristic accuracy, yet the knowledge that the ancients possessed of the actual nature of epilepsy reveals a sad mixture of ignorance and superstition combined, bordering on barbarism. Since the days of Hippocrates every century has borne in its medical literature conspicuous accounts of its mysterious manifestations, hence for over twenty centuries epilepsy has passed among men as a something too intangible to explain by any known law or process, and far beyond the scope and power of any therapeutic measure so far devised to arrest its pernicious effects upon the brain and other organs of the body in but very few of its numerous victims.

In the past twenty years, however, more actual progress has taken place in our definite knowledge concerning its true nature and character than in all the preceding centuries, and it is to this particular period that we are indebted for much of the information that supplies our text and that which we desire more particularly to emphasize. In order to fully realize what has been accomplished in this epoch-making period it is necessary, at the outset, that we study carefully the historical data associated with the gradual evolution from a series of extravagant and absurd hypothetical conclusions and superstitious beliefs to that of a regular succession of well-established scientific facts relating to the true nature and character of epilepsy.

---

*Read before the Mississippi Valley Medical Association on October 15, 1902.

Time forbids even a brief reference to the former, nor is it necessary, as the literature upon the subject is well known to all of you, but this paper would be manifestly incomplete if it failed to mention the leading features that rescued epilepsy from the domain of purely theoretical speculation and placed its study upon a more secure and accurate scientific foundation.

Prior to the celebrated dissections of Gall, at the beginning of the nineteenth century, the principal idea that obtained in regard to the brain by anatomists, and other scientists, was that of a semi-structureless mass, exhibiting certain ganglia, such as the striated bodies, the optic thalmi, the quadrigeminal bodies, and the pineal gland, but on the whole as a single organ or unit rather than as a group of organs. By an elaborate series of experiments and observations, Gall formulated a theory of his own concerning the brain and its functions, which was recognized as a decided departure from any then extant. Its essence consisted in a recognition of the brain as a multiform organ, that is composed of a number of nervous centers or organs, each endowed with special functions. This remarkable theory had the effect of startling the entire medical world, and the facts to which it appealed were severely criticized and wholly rejected by the then recognized scientific men. For instance, no less a personage than Sir Charles Bell termed it "The most extravagant departure from all the most legitimate modes of reasoning." Flourens, the French physiologist, also bitterly opposed it and was the first to undertake to prove its fallacy from a scientific standpoint. In 1822 he made the announcement before the French Academy of Medicine that Gall's theory was greatly misleading, and, by a brilliant series of experiments, undertook to prove to his audience that the brain was not a multiform organ, but that it acted as a whole, hence was single in its constitution, its several parts not possessing distinct functions. It is unnecessary to burden you with later investigations—suffice it to say that when Hood and Bouilland, a few years later, demontrated that disturbances of speech were always accompanied by disease of the frontal lobes of the brain. When Broca, in 1861, undertook definitely to locate the speech area, and when, in 1863, Hughlings Jackson of London, and Meyert of Germany, simultaneously announced to their respective medical societies that the anterior portion of the brain was concerned chiefly in motor acts, the former reaching his conclusions from the study of localized spasms and the latter from the observations of the lesions of general paralysis, it was very clear to all that Flourens's teaching needed further confirmation, and, in 1869, Fritch and Hitzig of Berlin undertook to verify it. Their conclusions proved beyond doubt the fallacy of Flourens's monistic theory of the brain, which were again verified by Ferrier in 1873, who also demonstrated that not only were the anterior lobes of the brain chiefly concerned in motor acts, but that the posterior portion was largely sensory in character, besides defining each special sense to a definite region of the brain. Thus the doctrine so vigorously taught by Flourens, and believed by the great mass of medical men, became wholly untenable, and the original views advanced by Gall and so ably supported by Broca, Hughlings Jackson, Fritch, Hitzig, Ferrier, Horsley, Gowers, Schaffer, and, within the last decade, by our own Dana, Starr, Sachs, Dercum, Mills, Berkley, Collins, Hammond, Mitchell, and a host of others, was fully proven, and to-day reigns supreme, constituting the science of cerebral localization.

Now, upon the recognition of this science and the facts to which it appeals hinges our modern medical conception of epilepsy. Your attention has, therefore, been purposely directed to this brief summary of historical data, because when Hughlings Jackson, in 1873, advanced the theory to the effect that in epileptic attacks the cells of the cerebral cortex undergo explosive discharges, he unconsciously defined the line of demarcation between empirism on the one hand and scientific truth on the other in the study of epilepsy. Late investigation, both clinical and pathological, proves conclusively that epilepsy is essentially a symptom of brain disease, confined chiefly, if not altogether, to the cortical cells of the cerebrum. In order, therefore, to comprehend fully what the term epilepsy implies presupposes a thorough knowledge of the structure and functions of the brain, as well as the nature and character of the lesions causing their derangement. As a primary proposition, therefore, and that to which all others refer (more especially when crime has been committed by an epileptic) is the extent to which the brain and its functions are impaired by the pernicious influence of the prevailing epilepsy, or how far this interferes with the individual's power of self-control. This at once raises the question of the mental responsibility of the accused epileptic. Now, the correct solution of this problem involves questions of the highest medicolegal importance, and, at times, transcends in complexity all other questions with which expert testimony has to deal.

From a purely medical standpoint, however, the expert must, of necessity, pay especial attention in every case to its pathogenesis, beside recognize the true significance of certain etiologic as well as pathologic factors associated with the various manifestations of epilepsy. Recognizing epilepsy as a symptom of some brain disease, we also know that it may occur from various causes, both congenital and acquired, but its chief etiological factor, and that which is now universally held, is that its presence is largely due to hereditary defects or some family inheritance. Theorize, criticize, or philosophize as we may concerning it, nevertheless the law of heredity is as potent to-day in the moulding of human character and the shaping of destiny as it was in the days of the patriarchs, and its close relation to epilepsy cannot consistently be ignored. Time forbids further enlargement upon the great significance which this one element alone furnishes us in explanation of the pathogenesis of epilepsy—suffice it to say that faulty inheritance is the responsible agent for many of the strange vagaries seen in epilepsy, and which at times culminate in actual mental alienation. From the foregoing it is clear that epilepsy presents itself in various forms that render it subject to classification. Hence idiopathic or ordinary epilepsy is seen, clinically, in three rather distinct types of attacks: (1) The less severe or minor attacks constitute petit mal, (2) the more severe ones, grand mal, (3) while the larvated form or psychical epilepsy is characterized by various mental and physical automatic states. In addition to these, Jacksonian epilepsy is recognized by the periodic character of the convulsions, which are of a primary local nature and often unattended with loss of consciousness. Symptomatic epilepsy is a form due to gross organic changes in the brain, producing convulsive attacks. In addition to those cases due to trauma, epilepsy also occurs in connection with other diseases, such as hystero-epilepsy, syphilis, and alcohol, besides the acute infections, but there are no special forms other than those mentioned arising from these complications. As already remarked, the most frequent results of epilepsy is mental deterioration, which, sometimes, amounts to true insanity. All authorities agree that epileptic convulsions when long continued, in some degree at least, impair the mental faculties, and that this mental weakness presents all degrees from a mere dulling of the emotions, sensibilities, and will-power to an absolute loss of all these, amounting to true dementia. The amount of mental failure, however, varies greatly in different individuals, and is not always dependent upon the duration of the epilepsy. It is even claimed that epilepsy and great mental strength, amounting to intellectual genius, are not incompatible, and while this in part may be true, yet in such cases it must be confessed that this is rare and exceptional, and the attacks are usually of a mild or transitory character. Hence the validity of universal medical experience, viz., that well-established epilepsy is a sure sign of biological inferiority still remains intact. By virtue of its complicated nature, however, epilepsy becomes a common and convenient plea of defense for crime, hence the mental responsibility of an epileptic has become one of the most momentous medico-legal questions of the day, and we, as the exponents of medical science, are called upon to assist the authority of law in meting out justice when epilepsy becomes associated with crime, and, more especially, in case of murder. In assuming this dignified and lofty function, we are called upon to consider not only the mental condition of the accused epileptic, but also to pass upon his responsibility for the crime, it is, therefore, at the outset, important to remember that it would be manifestly improper to exonerate a criminal simply because he was subject to convulsions, equally culpable also to condemn because convincing symptoms of epileptic insanity had not been observed or proven. In thus considering the mental condition of the epileptic, and especially his responsibility for criminal acts, we must, therefore, recognize the extent to which mind control has been impaired by the epilepsy as well as the existence of epileptic insanity. In case, for instance, where an epileptic has committed murder, the problem to be solved is usually whether the accused was insane, and if he knew the difference between right and wrong at the time he committed the deed. If he did, he is then, says the law of Missouri, mentally responsible for his crime, sane or insane, and his punishment is fixed by statute, to be death on the gallows. Now the legal aspect of insanity, whether it be epileptic or any other form, differs radically from the medical aspect, and, because of this, gross injustice is sometimes allowed to pass for justice even by those who would otherwise be just. Thus the insane criminal is sometimes convicted legally, but not medically, because he happened to know the deed he committed was wrong, besides being competent to relate all the details of the crime. Now it would seem a useless expenditure, and even waste of time, for me to attempt to show the fallacy of this legal view of insanity, the essence of which recognizes no degree of the loss of the power of self-control. It is simply surprising, however, to find how few medical men (much less lawyers and jurymen) believe an insane man may premeditate and plan to murder, and, after a varying length of time, execute it with a marked degree of intelligence and cunning, and when arrested be able to explain all the particulars in detail, besides acknowledging that he knew it to be wrong and in violation of the law, as well as recognizing the stipulated penalty for such a crime, and yet in spite of this be mentally irresponsible for his deed. Medical science and experience, however, teach us that all the details referred to can be done by an insane man. Hence I contend that the legal test of mental responsibility when alone applied often miscarries the true specific purpose of meting out justice to the criminal. As it stands to-day, the test of criminal responsibility before our courts lies in the proof of possession of reason and free will; when both these are present the party is held responsible, when either is absent he is not held responsible. Professor Ordronaux of the Columbia College of Law, New York, says, according to this legal definition, "By reason is meant an intelligent comprehension of the circumstances in the midst of which one is placed, and by free will is meant the power of doing or abstaining from doing a particular act or thing." Now the opinions of competent medical men to-day are agreed the world over that many an insane criminal knows right from wrong, and can often relate intelligently all the details of his crime, beside plan and premeditate it, as well as seek to evade arrest, and yet, at the same time, be irresponsible for his actions. Those of you, however, who desire to study this phase of my subject more closely can do so by consulting Taylor's "Medical Jurisprudence," page 678, fourth edition, in which several such cases are cited, many of whom, however, were acquitted by the court, although they knew full well the quality and nature of their criminal act, thus recognizing right from wrong.

In dealing with the question of criminal responsibility, it would seem that much of its complexity would be removed if the criminal code proposed by Mr. Justice Stephens of London could be universally adopted in our courts of law. This appears to the writer not only fair but just, and with its ruling every medical man can agree for its substance, proposes to make the individual's power of controlling his actions the real test of mental responsibility. It is as follows (see Clouston on "Mental Diseases," page 428): "No act is a crime if the person who does it at the time when it is done is prevented either by defective mental power or by any disease affecting his mind from controlling his own conduct, unless the absence of the power to control has been produced by his own default. The justice of such a rule as this is clear, although its application requires extreme care and judicious discrimination. More especially is this true when it pertains to the latter clause in which provision is made for punishment in cases where the individual is responsible for his mental derangement. Your attention has already been called to the fact that epilepsy may be congenital or acquired, hence the importance of its etiology and the relation it bears at times to the crime is self-evident. No one doubts, for instance, that syphilis and alcohol sometimes become potent factors in not only the causation of epilepsy, but also promotes the homicidal acts of the epileptic. Hence the relation of these to criminal responsibility would seem to be plain, as these are matters of free choice and hence subject to individual will power. In the majority of cases, however, of epileptic insanity the loss of power of self-control is so clear that it requires no special study to recognize its true relation, but occasionally there is a departure from the recognized principles which govern its diagnosis, and it is more especially in those cases in which medical testimony is liable to conflict, and proves of no special value in solving the problem of criminal responsibility, in all such cases, however, even when the murder is known to have been committed by an irresponsible epileptic the law should be amended to allow its holding them under rigid medical surveillance for the rest of their lives. In this connection careful discrimination must be made between punishment on the one hand and medical treatment on the other. No insane criminal epileptic should be punished (as this term is commonly understood) unless his epilepsy was brought about by his own fault, and even then his pitiable condition appeals to medicine more than to law. Private opinion should not be subject to public sentiment unless the facts in the case are strictly in accord with the consensus of medical teaching and experience concerning the true nature of epilepsy. All authorities agree that irritability, impulsiveness, and aversion to control are the marked characteristics of the epileptic psychosis, but even these unfortunate traits are subject to discipline by proper and appropriate medical treatment. In true epileptic mania the criminal act is usually unpremeditated, motiveless, and accompanied by impairment of consciousness and temporary loss of memory—conscious anger in an epileptic should, therefore, be distinguished from true epilepticmania. Time forbids further enlargement upon the special characteristics of epileptic insanity—suffice it to say that all authorities recognize that homicide is its legitimate product, and much leniency should be allowed in every case in which murder is committed by one who is known to be subject to true epileptic paroxysms.

As a remedy for the present unsatisfactory method of securing expert medical testimony, the question of the mental responsibility of the epileptic should be decided by an impartial medical commission, appointed by the court, which again may be referred to the local medical societies to name its member, and then examination should be made and report returned to the court prior to the trial, and wholly independent of the lawyers engaged in the trial, and suitable compensation for such service should be allowed by a fixed statutory law. In conclusion, it would seem that the following deductions are admissible: (1) That epilepsy is a symptom of some brain disease; (2) That its continual presence tends toward mental deterioration; (3) That the mental responsibility of the epileptic depends upon the extent to which mind or self-control has been impaired by the epilepsy; (4) That the legal test of insanity is not sufficient, as mental irresponsibility is not incompatible with a knowledge of right from wrong; (5) That epileptics are, to some degree at least, responsible for criminal acts, more especially when the epilepsy is produced by their own fault; (6) That criminal acts of epileptics appeal to medicine rather than to law for their proper adjudication; (7) That in all cases of murder in which epilepsy is proven the law should be amended to allow of like commitment to an insane hospital rather than to the penitentiary; (8) That the mental responsibility of the epileptic in case of murder should be referred to a medical commission, appointed by the court, which again may be referred to local or county medical societies to name its members:

ALTMAN BUILDING.

The Prophylaxis of Ophthalmoblenorrhœa Neonatorum with Reference to the Use of Silver Acetate.—Elmer Scipiades reviews the statistics of this affection, which, previous to the introduction of Credé's method, show a morbidity of 13.5 per cent., which since then has been reduced to 0.6 per cent. As is well known, the procedure rests upon two cardinal points: (1) The repeated antepartum disinfection of the maternal vagina with irrigations of bichloride; and (2) The instillation of one drop of a 2-per-cent. solution of silver nitrate into the conjunctival sac of the child before cutting the cord. In spite of the overwhelming evidence in favor of the method, the doubt still remains as to whether or not it is the ideal one, and the author has attempted to discover whether any of the countless modifications proposed accomplish as much as the silver nitrate without producing the disagreeable reaction that so often follows the use of this agent. Of all of the substitutes for the Credé disinfectant, such as bichloride, carbolic acid, salicylic acid, sulphocarbonate of zinc, B-naphthol, chlorine water, permanganate of potassium, resorcin, thymol, icthyol, oxycyanate of mercury (1-2,000 Axenfeld), concentrated solution of boric acid, formalin (1-1,000 Castillo), sterile water and iodoform, the one that has come nearest to it in point of efficiency is protargol. In view of the fact that, although other organisms, such as the diphtheria bacillus, the micrococcus the pneumococcus, the coli bacillus, the Week's bacillus, the staphylococcus albus, and aureus, and even the pseudo-influenza bacillus, may produce the condition, still, the vast majority of the cases of infantile ophthalmia are gonorrhœal in origin, this preparation of silver which has shown itself so hostile to the gonococcus in other regions, might be expected to be equally serviceable in the eye. As a matter of fact, its efficacy is about equal to that of the silver nitrate, but the intensity of the reaction produced by solutions of sufficient germicidal power is also nearly on a par with that attending the use of the older antiseptic. A preparation possessing undoubted theoretical advantages is silver acetate, which has the property of not forming solutions of greater concentration than 1 per cent. at room temperature. Zweifel's statistics, and those of the author, both indicate that in it the substitute for the caustic salt of the Credé method has been found, since it keeps the morbidity down to 0.23–0.24 per cent. and produces a reaction which is nearly always entirely negligible. The method of use is as follows: The eyes, if possible, even before they are opened, are wiped with a dry cloth in the direction of the inner canthus. The cloth should be dry, in order that the conjunctional secretion shall not be diluted and its reducing power decreased. The 1 per cent. solution of silver acetate is then dropped in at the inner canthus, and the lids are opened and closed several times to insure thorough distribution. A little weak sodium chloride solution is then put in to completely neutralize any excess of the disinfectant.—*Volkmann's klinische Vorträge*, No. 340, 1902.

Crusade against Consumption.—Dr. T. N. Kelynack, writing in the *London Hospital*, October 4, says that in the conduct of a comprehensive campaign against consumption, the following measures are requisite: (1) The recognition and protection of all persons predisposed to tuberculous infection; (2) The detection of the earliest manifestations of consumption; (3) Notification of all consumptives; (4) Private Sanatoria or effective home treatment for the affluent; (5) Public dispensaries or outpatient's departments; (6) Public hospitals, situated on the borders of towns and cities, for observation of patients and treatment of acute cases; (7) Public sanatoria, situated in the country, but, if possible, readily accessible; (8) Seaside sanatoria for children; (9) Convalescent homes for consumptives; (10) Homes for advanced cases; (11) Country colonies for "arrested" cases; (12) State hospitals, sanatoria, and homes for the dying, and for all destitute cases.

EPIDEMIC INFATUATION—THE DOUKHOBOR PILGRIMAGE.

A RECRUDESCENCE of medievalism, strange in modern eyes, is the movement now taking place among the Doukhobors in the Northwest Territory of Canada. Some sixteen hundred of these people turn loose their stock, and, headed by "John the Baptist," with his long arms threshing the air, and crying that he sees the Messiah in the distance, cast away hats, coats, shoes, and march with their women and children (of whom some are born and some die on the way) "seeking Jesus," and saying, "The Lord will care for his people; if we die it is for Jesus's sake and we are satisfied." This state of affairs would, indeed, be strange were it to break out suddenly among a happy and contented people. But no more in human affairs than in the natural sciences does something come from nothing. From the day when Moses led his downtrodden host forth from the land of Egypt, such movements have usually marked the stress of hard conditions upon peculiar mental temperaments. In other words, they are the outcome of reaction against calamities, such as epidemics, famines, and persecutions, and seem to be born of the idea that, as the condition of this world is too bad, it is to another that man's gaze must be turned. Such conditions always bring fanatics to the front and secure for them a hearing; and from amid the innumerable mental variations present at any given moment in the human species, by a process of accretion, like becomes assimilated to like, and an aggregate is formed such as the one now in question.

The history of the Doukhobors shows that they form no exception to the rule. The sect crystallized itself from among the peasantry of Russia somewhere about the middle of the eighteenth century. It can best be described as a combination of the pure morality and simplicity of the Quaker with the community principle of the "Perfectionists." In Russia it was now tolerated, now persecuted on account of its repudiation of the ritualism of the Orthodox Church. Some five years ago the Doukhobors began to emigrate to Canada, but only to find that there, too, they must conform to certain laws. June 22, 1901, they demanded of the Canadian Government that: (1) Individual property constituting "an evident violation of the will of God," land be ceded to them communally, as to the Indians; (2) Marriage being legal "only in virtue of a pure sentiment of moral ttachment between man and woman," registration on books of state is a violation of the laws of God," and they demanded to be subjected "to no human institution concerning nuptial unions which are the domain of God and the conscience"; and (3) The inscription of births and deaths upon the registers of the civil state is not less unacceptable, because "the Heavenly Father knows whom he sends to the world and whom he withdraws from it, and the will of God is alone necessary and important for man." To the refusal of the Government the Doukhobors replied: "We understand that the Government has much difficulty in satisfying our demands, and consequently in limiting the intrusion of laws into our life. . . . Now we are obliged to pray you to be sufficiently good to permit us to remain in Canada until we find another country to fix ourselves, or until we shall be convinced that men who wish to establish their life upon a Christian basis have no longer a place upon the earth." Informed by the Government, July 28, 1901, that they ought to receive their land without delay, as otherwise it would be impossible to keep it for them and others would come and install themselves upon it, the Doukhobors refused, saying that if one holds absolutely to inscribing the homestead in the name of some one, "let it be done, but for us it is necessary that the land should be indivisible. . . . We live as a single farm." Strannik, from whom we have taken the foregoing facts, reports (*Revue de Paris*) that the majority of the Doukhobors appear to understand that nowhere else could they find better terms. But when he wrote, a few ardent and unquiet spirits had already issued an "Appeal to Humanity" asking that they be told whether there exists anywhere a place where they can be supported, or where they can establish themselves and live without being obliged to infringe the laws of their conscience and of truth. Strannik well remarks of the authors of the "Appeal," that they are spirits always more taken with an impossible ideal; and spirits for whom all compromise with their conscience would be more painful than persecution. ' Perhaps the realization of their dream is for them less dear than the perpetual effort of that pursuit, and perhaps they believe, as it is said in the doctrine of Christ, that those are blessed who hunger and thirst for truth." Presumably the present migration is an outcome of the dispute over the land, in individuals whose stubbornness where principle is concerned has been repeatedly shown. Strannik's statement that the majority have accepted the situation seems to be borne out by the number on the march, viz., 1,600 out of more than 7,000. The practical working out of the problem will probably involve the death of many from exposure, and, very likely, the incarceration of the leader in an asylum. To judge from the ease with which our immigrant population becomes acclimatized by the second generation, there is, however, ground for the hope that these simplehearted Russian peasants will gradually yield to the influences of a better environment.

Marked Increase in Contagious Diseases in Philadelphia.—For the week ended October 25 there were reported to the Philadelphia Board of Health twelve new cases of smallpox, forty-seven of diphtheria, sixty-five of scarlet fever, and ninety of typhoid fever, a considerable increase of each over the number during the preceding week.

THE SUBCUTANEOUS USE OF PARAFFIN.

The restoration of facial deformities to normal conditions by the operative methods at our disposal has always had some drawbacks and elements of dissatisfaction. Our best efforts have frequently failed to correct the disfigurement, and sometimes, in spite of everything, the last condition of the patient has been worse than the first. The fundamental reason for this is the uncertain behavior of cicatricial tissue, and the accidents which may happen to transplanted flaps, upon which almost all plastic operations depend. The efforts of surgeons to find some foreign substance which could be safely introduced under the skin, and which would remain there, show that the use of the tissues of the patient's body must, in a large proportion of cases, be supplemented by some substance which will fill space and give form in order to eradicate the deformity completely. Many such materials have been used, and they are so well known that it is not necessary to enumerate them.

Comparatively recently surgeons have had their attention drawn to what seems, in many respects, to be nearly an ideal substance for subcutaneous use—that is, a paraffin with a melting point somewhat above the ordinary temperature of the body—and, since the suggested use of this material, a number of cases, chiefly facial deformities, have been reported in which it has been used. A communication by von Angerer of Munich in *Beiträge zur klinische Chirurgie, Band* 53, *Heft* 3, gives a minute account of three cases of "saddle-nose" in which the paraffin method was employed, and an examination of this record discloses much of interest. All the cases were typical of the peculiar deformity, and all were treated in the same way by the injection of about two and one-half cubic centimeters of warm paraffin, the melting point of which had been found previously to be such as would permit solidification at the body temperature. The anæsthetic was 1 per cent. cocaine solution, and an ordinary hypodermic needle was used for introducing the paraffin. After the injection any moulding could be done that seemed desirable, and a cold, moist dressing was applied for twenty-four hours. In two of the cases there was no special wound reaction, and after a few months the injected mass felt firm and hard, apparently more or less surrounded by fibrous tissue. In the third case an area of skin over the injected mass sloughed, and the paraffin came away. It was necessary later to repair the defect thus caused by bringing down a flap from the forehead, and the operator was considering, at the time of the report, whether it would be advisable to attempt a new injection or not.

Corning, Gersuny, and others have suggested and tried paraffin injections in conditions other than facial deformities, and a number of favorable results have been reported. Paraffin has been injected into the uvula after staphylorrhaphy, in order to increase the size of the part and so to facilitate closing of the nasopharynx during articulation; it has been injected around the margin of a vesicovaginal fistula which did not prove amenable to operation; it has been tried in cases of hernia of various kinds; and, in fact, its use has been suggested in a variety of conditions in which firmness and mass are required to get an approximate return to normal conditions.

Reports so far indicate that the procedure under consideration is safe and unattended by unpleasant accompaniments, but there are occasional occurrences which require elucidation and explanation; and, furthermore, it is desirable to know, if possible, what conditions are most favorable for the method in any given case. A certain number of cases have exhibited a violent wound reaction, though cutaneous sloughing, as in von Anderer's case, must be very infrequent, and a contributing cause, at least, of this may have been the injection of paraffin into the skin, or the use of too great a quantity. It is also well to note that in case the skin is adherent to or very close to bone, there is considerable danger of causing too much tension by the injection.

In one reported case the injection was followed by sudden and serious collapse and the rapid development of unilateral amaurosis. The former was recovered from, but the blindness remained. The explanation of this was that some of the paraffin entered a vein, probably the dorsalis nasi, and thence was carried into the ophthalmic vein, probably causing thrombosis. This occurrence emphasizes the necessity of avoiding veins with the needle, and it has been suggested, apparently with good reason, that the injection should be made when the paraffin is at the point of solidifying, so that it will remain in one place in the tissues. Many thousand injections of mercury, in unguent form, have been given in the treatment of syphilis, and accidents are almost unheard of, so that where provision is made as suggested above, the danger is infinitesimal. Of course the veins in the face are very large in proportion to those in the regions selected for the mercurial injections, and, consequently, additional care must be exercised. Cases in which the skin is adherent to bone or other firm tissue, or in which the cicatrix in the region of the deformity is very dense, are the least favorable for this sort of operation; and it is somewhat doubtful whether it is a good plan to attempt to free the skin in such cases by the subcutaneous use of a narrow knife, which will certainly, to some extent, interfere with the blood supply of the skin. However, this must be done occasionally, or the tension caused by the injected paraffin will be too great. How the paraffin is taken care of in the tissues is still somewhat uncertain. It has not yet been proved whether the substance acts like an innocuous foreign body and remains embedded in an accretion of fibrous tissue, or whether there is a gradual chemical process going on which eventually removes the foreign material, leaving a mass of new tissue. As far as the patient is concerned, this is not an important question however. It would seem that by a careful use of this method of paraffin injection, we have at our command means for relieving patients of disfigurements which often cause great distress and mortification, and further reports of experiences will be welcome. Operations on the face will naturally constitute the great majority, for obvious reasons.

Free Hospital for Epileptics.—The State Convention of the Directors of the Poor at Somerset, Pa., has recommended the purchase of Highland Inn and one hundred acres of ground for the purpose of establishing a State hospital for epileptics.

THE ETIOLOGY OF BERIBERI.

Dr. Patrick Manson read before the meeting of the British Medical Association of this year a paper on the above subject. Little is accurately known concerning beriberi, and there is much difference of opinion as to its diagnosis. Dr. Manson says it is known for a fact that the term has been applied to ankylostomiasis, to epidemic dropsy, to sleeping-sickness, and to a variety of other diseases. Sometimes experienced tropical practitioners include several specifically distinct forms of neuritis under this one term—beriberi. Clinically beriberi—according to Dr. Manson—is a multiple peripheral neuritis, and is distinct from arsenical neuritis, much as it may resemble this condition in its symptoms. Again, beriberi is often mistaken for malarial neuritis; the distinguishing features, however, between the two are that, in the former condition, there are marked proneness to cardiac implication; in the latter, an impairment of memory. The following features are suggested as a basis on which to found our recognition of beriberi as a distinct form of multiple peripheral neuritis, and as more or less distinguishing it from other pathological groups, with neuritis as their leading clinical phenomenon: (1) Our ignorance of its cause; (2) Its occurrence as an endemic and epidemic disease; (3) Its proneness to produce cardiac disability and dropsy; (4) Non-implication of the cranial nerves, with the exception of the pneumogastric; (5) Non-implication of the intellectual and emotional centers; (6) Rarity or complete absence of trophic skin lesions; (7) High rate of mortality under certain conditions.

It is further contended in this paper that: (1) The immediate cause of beriberi is a toxin; (2) The toxin of beriberi is produced by a living germ; (3) The toxin-producing germ operates in some culture medium; (4) That culture medium is located outside the human body; (5) The toxin of beriberi does not enter the human body in food; (6) It is not conveyed in drinking water. Proofs are numerous in support of this assertion.

In conclusion, Dr. Manson says that, allowing these propositions, it must be concluded that the virus of the disease is conveyed to man by the air, or through the skin by contact, or by means of some insect which inserts itself under the skin, or by a combination of some of these ways.

Dr. Manson's views with regard to the etiology of beriberi are original, but this is the case with most of his hypotheses. The commonly accepted opinion as to the cause of the somewhat mysterious Asiatic disease has been that the consumption of rice had much to do with it. This belief has been weakened by a paper read by Dr. Travers at the meeting of the British Medical Association, in which he gave the results of experiments carried out by him going to show that food has no effect upon the causation of the disease.

Dr. L. W. Sambon, in a paper read at the same meeting, disagreed with the conclusions reached by Drs. Manson and Travers, and said that "he failed to see how they can sweep away the enormous amount of evidence brought forward against rice not only by Baron Saneyoski, in his admirable report on the experience of the army and navy of Japan, but by the great majority of physicians of all times who studied the disease in China, Japan, the Dutch Indies, and Brazil."

The evidence in favor of rice—at any rate as a contributing cause of beriberi—is weighty, voluminous, and of long standing. The disease is a prevalent and especially deadly one in the far East, and it would be of great service to the inhabitants of that part of the tropics if its etiology could be clearly defined. If the true cause of beriberi were known, its treatment would be conducted with greater hope of success than is at present the case.

The Undesired and Unexpected Actions of Drugs.

Sir Lauder Brunton read a paper dealing with this matter at the recent meeting of the British Medical Association. Belief in the efficacy of drugs is not nearly so strong with the medical profession now as it was even twenty years ago, and our forefathers' faith in the remedial and curative properties of medicine would be looked upon at the present time as absurd. Nevertheless, the general public appears to retain unabated confidence in the beneficial action of internal remedies, and takes its patent medicine with more zest than ever before.

Sir Lauder Brunton, referring to the subject-matter of his paper, said: "Drugs may exert an unexpected action either by (1) failing to produce their usual effect; (2) having an excessive effect, or (3) having an unusual effect. In discussing the action of drugs we must always remember that it is really the reaction between the drug and the organism which we are considering, and an alteration in the effect may be due either to the drug or to the organism."

Drugs may deteriorate by being kept too long, or alterations in the effect of drugs may depend very much upon changes in them after they have been actually swallowed. "Again," says Sir Lauder Brunton, "the relationship of medicine to meals is very important, and, perhaps, of this no better example can be given than arsenic, which, if taken in full doses before a meal, will almost certainly cause gastrointestinal irritation, whereas the same dose will produce no disagreeable symptoms if taken immediately after a meal, so that the medicine becomes diluted by admixture with the food in the stomach."

With regard to the action of narcotics, the writer says: "Excitement of the circulation tends to counteract the effect of a narcotic upon the brain, as is well known in cases of opium poisoning, where the circulation is kept active by keeping the patient walking and by applying a painful stimulus, such as a strong faradic current, to prevent coma."

That drugs somewhat frequently do not have the desired effect is the experience of all physicians. It would, perhaps, be well to follow the advice of the writer of the paper just quoted, to procure medicine pure and good, to administer it judiciously and at the proper times, and, finally, to use it with due regard to the idiosyncrasies of the patient.

Is Water a Food?

In a paper read before the American Pharmaceutical Association in September, 1902, Mr. John Uri Lloyd makes a plea for the recognition of water as something more than a mere solvent—in fact, as an integral and necessary constituent of the tissue elements, and of foods: "The question is, has the water that is used in the making of a soup, by the action of heat, simply dissolved certain salts and tissues, or has it combined with organic constituents in a way that will make a nourishing liquid or a series of water combinations, in which water exists, it is true, but with altered qualities?" In other words, has the foodstuff been partially hydrated *en route*—been partially predigested, so to speak? Water being a "saturated" molecule, no one would, of course, maintain that by and in itself it is a food. But Mr. Lloyd's contention that foods are foods only by reason of *chemically-combined* water has considerable plausibility. Two questions are present, that of availability, and that of food value proper—that is, the amount of energy contained. The latter is evidently not affected by the present question. But availability may be dependent upon the fact and degree of hydration. For example, if grape sugar, $C_6H_{12}O_6$, be treated with strong sulphuric acid, it gives up all its hydrogen and oxygen in the form of six molecules of water, and there remains a spongy mass of carbon, valueless as food. Similarly, it may be that many of the organic compounds are not the same, either chemically or physiologically, after more or less water has been subtracted from them. On the whole, therefore, Mr. Lloyd's paper is an interesting and suggestive one from the standpoint of dietetics.

THE INCREASE OF TUBERCULOSIS AMONG NEGROES.

The negro race in this country is in a high degree susceptible to tuberculosis. The truth of this statement has been emphasized of late years by the decided increase of the disease in Louisiana and in other States, in which there is a large negro population. An article in *The Sun*, November 2, says that there is alarm in the medical profession of Louisiana, owing to the rapid spread of consumption among the negroes of that State. According to the writer of this article, "There has been improvement as regards the disease among the whites, owing to better sanitary precautions, but the physicians at all the recent meetings of the Louisiana State Medical Society warningly pointed out that this improvement could not long continue if the infection remained so prevalent among the negroes, who constitute practically all the domestic servants. The mortality from tuberculosis among the negroes in New Orleans is four times as great as among the whites; in the country parishes it is from six to ten times as great. What is worse is that, while the disease is growing less prevalent among the whites, tuberculosis is spreading among the negroes, and is nearly twice as prevalent as it was twenty years ago. The physicians all agree that the most serious negro problem confronting the whites to-day is the sanitary condition of the negro race."

The manner in which negroes live, their utter lack of hygienic surroundings, their carelessness in eating, drinking, and in clothing themselves, are all potential factors in originating and spreading the disease. But at the same time the negro would appear to have a racial predisposition to tuberculosis. Its course, too, in the colored individual is far more rapid than in the white man. The disease kills a negro with surprising celerity. It is stated that among the whites in Louisiana 25 per cent. of the cases recover and 60 per cent. improve under good treatment. Dr. J. M. Barrier of Richland Parish declared that he had in his long practice seen improvement in only two negroes suffering from consumption, and both of these were mulattoes. He had never seen a full-blooded negro survive consumption more than twelve months. Reports from eighty physicians showed that 60 per cent. of negroes treated by them for consumption died within the year, and only an infinitesimal fraction showed any improvement.

Not only for the sake of the negroes themselves, but in defense of the entire community, it is imperative that steps should be taken to check the spread of tuberculosis among the negro population. The negroes in the South are allowed to live under conditions which would not be permitted to a white man. Such indifference to the physical well-being of the negro race is a great mistake, and a menace to the health of the white inhabitants.

The recommendations adopted at the recent meeting of the Louisiana State Medical Society were: First, to teach the negro, by a missionary movement, the danger of consumption and how to treat it; and, secondly, to require the boards of health to devote more attention to the sanitary conditions of the negro quarters of the Southern towns.

BACTERIA OF THE MOUTH AND DISORDERS OF DIGESTION.

The state of the mouth and condition of the teeth have much to do with the action of the digestive organs. If a person has carious teeth it may, as a rule, be taken for granted that his digestion is not as it should be. The proper care of the teeth and mouth is an important factor in the preservation of health.

Mr. E. W. Roughton has published in recent issues of *The Lancet* a series of lectures delivered by him on "Bacteria of the Mouth and Disorders of Digestion." He said in part:

"The influence of an unclean mouth on the disorders of digestion has doubtless been hitherto much underrated. As Miller remarks, we frequently meet with persons who carry such filth in their mouths as they would never tolerate on the skin. The physician who must insert his finger into such a mouth is sometimes well-nigh overcome with disgust, the *fetor ex ore* is insufferable, the teeth are covered with a thick deposit in a state of active fermentation, the gums are intensely reddened, inflamed, and suppurating, and where decayed roots are present, which is usually the case, chronic abscesses produced by them continually discharge suppurative and putrefactive products into the oral cavity; and with all this individuals expect to enjoy good health.

"For years it has been recognized that many disorders of the stomach and intestines owe their origin to local fermentative and putrefactive processes. There can be no doubt that the mouth acts as a breeding place or starting point for a certain proportion of the bacteria which set up fermentation in the stomach. The view formerly held that germs which had been swallowed perish in the stomach has been shown to be incorrect. Sucksdorf estimated that out of every 100 bacteria found in the fæces ninety-seven are derived from the food and drink, and three only from the mouth itself when the latter is clean and well-cared for. In neglected mouths, however, as many as 30 per cent. of the bacteria present in the fæces may be regarded as derived from the mouth. It may be readily inferred, therefore, that the condition of the mouth may very seriously influence the functions of the alimentary canal. Even more serious results may follow neglect of the teeth. There is more than one case on record where the bacteria of the mouth have set up a gastritis of the wall of the stomach itself."

The warning of Mr. Roughton with regard to the extreme importance of caring for the mouth and teeth is well-timed. The disregard evinced by many persons for these points is remarkable. Early decay of the teeth is decidedly on the increase, and doubtless may be attributed to the consumption of large quantities of meat, rich food, and, among women, sweetmeats. The inhabitants of the

United States are, nevertheless, more heedful of their teeth, on the whole, than the people of Europe. While a stranger to this country must be struck by the large number of persons who carry in their teeth the marks of the dentist's handiwork, yet at the same time he cannot but observe that, so far as whiteness is concerned, the teeth of the majority of the population of the United States compare most favorably with those of the European people. Some English journals occasionally comment in caustic terms on the tendency of American journals—including those devoted to medicine to indulge in spread-eagleism, and to unduly extol everything in connection with their own country. This feature is undoubtedly somewhat of an amiable weakness on the part of our journalists; but with regard to American dentists, the fact is undeniable that they are absolutely in the lead in the practise of their profession, and, furthermore, are unsurpassed in the mechanical branch.

Nevertheless, here as elsewhere, a very large number of individuals exhibit an extraordinary negligence in the care of their mouths and teeth, and it cannot be too strongly insisted upon that such neglect, if long continued, will infallibly lead to unpleasant, and sometimes to grave, results.

The Prevalence of Morphinism.

Dr. Crothers is one of the foremost advocates of temperance in the world, and his writings on inebriety and the drug-habit have won for him a well-deserved reputation as an authority on the matter.

His latest book deals with morphinism in all its phases, and he has collected therein a quantity of interesting facts with respect to this habit. He points out that the possibility of concealing, for a considerable time, the morphine habit has rendered it a most seductive vice, and declares that its practisers may be found by the thousands in France and Germany, where entire villages even are said to be filled with morphine takers.

It is gathered from the sale of morphine in some of the large cities of the United States that not half of the amount sold is traceable to the legitimate demands of physicians and hospitals, and the just inference is that there must be a large secret consumption of the drug. Statistics of the sales of the drug stores tend still further to confirm this belief by showing that a very large part of the total is bought by laymen.

As regards morphinism in relation to the medical profession, an editorial was published in the Medical Record, November 4, 1899, treating of the matter. Dr. Crothers had at that time just stated that about 21 per cent. out of a total of 3,244 physicians residing in the Eastern and Middle and some of the cities of the Western States were found using spirits or narcotics to excess. Morphine is the drug most commonly used by all classes. "On the frontiers and in centers of great business excitement and nervous strain it is used more and more."

The assertion is made that a "hypodermic-needle mania" exists, and that in some parts of the States itinerant pedlers carry with them syringes, and will inject morphine into those persons who are willing to pay for the temporary relief from nerve strain or from pain afforded thereby.

The surrender of the victim to the habit is insidious. With some it is comparatively slow, with others rapid—according to constitution and temperament—but the end, if the vice is continued, is always the same—mental, moral, and physical ruin.

Crothers says that the morphine habit exhibits three stages of development. The first stage is that in which the drug is taken to relieve pain or bodily suffering, such as colic, neuralgia, rheumatism, spasmodic asthma, dysmenorrhœa, or insomnia. The effect of the injection is usually satisfactory, as relief is speedily obtained. Later, when recurrences of pain take place, the remedy is again resorted to. In insomnia and in conditions of worry and anxiety, attended with nervous exhaustion, the effects produced by morphine are often very pleasant, as it not only relieves pain, but produces a feeling of general exhilaration. The thought of becoming a victim addicted to the use of the drug and powerless to shake it off is not at this stage entertained by the patient, who takes it in strictly medicinal doses and only when needed. The second stage begins when the patient employs morphine for imaginary pains, and when he merely seeks pleasurable exhilaration for its own sake. After this the abandonment of the drug becomes difficult, and is followed by much discomfort and distress. Generally attempts are made from time to time to discontinue the habit, but in the majority of cases such attempts are unsuccessful. The person is now accustomed to use the drug at shorter and shorter intervals, and the craving which hitherto was only intermittent now becomes almost continuous. The third stage is marked by a continuous craving for the drug, and the quantities consumed are large.

The treatment of morphinism, even when its victims are confirmed in the habit, is by no means devoid of hope. The removal of the drug and the restoration of the functional derangements are, according to Dr. Crothers, practically simple, when the physician has full control of the patient and his surroundings. The treatment and after-care require far more skill and tax on our therapeutic resources. The abandonment of the needle at the start, and the change to some other form of opium or other narcotic to lessen the acuteness of the withdrawal symptoms, then the slow or rapid withdrawal of the drug, are the most practical means. The hot-air bath, with massage daily, or more frequently if necessary, is the most valuable procedure. Several drugs are also useful in treatment of morphinism. Suggestion and emotions of a vivid kind, such as religion, have been found in many instances to be most effective modes of treating morphinism.

When one considers the increase of morphinism, the impression cannot be avoided that the facilities offered to the public of procuring morphine and other narcotics are too easy. Again, as has been pointed out frequently, physicians are in fault when they prescribe morphine to allay pain or to compose nerve strain, without taking fully into consideration the possible ultimate result of such treatment. Unfortunately, in the case of morphine, the remedy in the long run often proves to be worse than the disease.

The Unreliability of the Microscope in the Diagnosis of Malignant Disease. G. Hamilton Whiteford says that he has seen the value of the microscope repeatedly and extensively tested in the diagnosis of all the more common varieties of malignant tumor. The result has been a series of shocks to his previously firmly-rooted belief, and he now holds that the microscope for purposes of differential diagnosis is perfectly unreliable. Hamilton of Aberdeen has shown microscopic sections of the tongue of persons over fifty-five years of age which present an appearance identical with that seen in epithelioma. He placed side by side with them sections of clinical epithelioma, and the most expert pathologists were unable to distinguish between the two. The author considers the naked-eye appearances and the clinical history of a case to be much more reliable than the microscopic appearances.—*The Bristol Medico-Chirurgical Journal.*

News of the Week

The Plague in San Francisco.—The menace to the country from the increasing number of plague cases in San Francisco, consequent upon the foolish denials by the Mayor and other officials of the existence of the disease, is beginning to excite alarm. The disease broke out there over two years ago, but the State and municipal authorities sought to conceal the fact for fear of injuring the business and commercial interests of the State and city. The officers of the Marine Hospital service, and back of them the Secretary of the Treasury, insisted that the full seriousness of the situation must be recognized, but the Governor declared that the State and municipal authorities were competent to deal with the situation such as it was. Californians generally denied that there was any plague in San Francisco, and the newspapers would not even mention the subject. Active measures were taken, however, and the conditions were improved for a time. Within the last few months the plague has gained new headway in San Francisco, and has even spread to Oakland, Berkley, and Davisville, and perhaps to other towns. Attention has been directed anew to this state of affairs by certain resolutions adopted at the meeting, two weeks ago, of the State and provincial Boards of Health in New Haven, Conn. Those resolutions denounce the San Francisco authorities for failing to stamp out the disease, and especially for seeking to suppress the full facts regarding the situation.

Post-Office Physicians Discharged.—The Postmaster-General has issued an order abolishing the position of post-office physician in all cities of less than 500,000 inhabitants. There were ten of these smaller cities having post-office physicians employed at an average annual salary of $1,050, so that the saving to the Government and the loss to the profession will amount to $10,500. This action was taken after consultation with the postmasters in the cities affected, who advised the Department that the office of post-office physician was not necessary.

Rush Medical College and the University of Chicago.—Conditioned upon the raising of $1,000,000 by the trustees of Rush Medical College not later than July 1, 1903 the trustees of the University of Chicago, it was announced to-day, have agreed to receive the medical school as an organic part of the university. The college and the university became affiliated four years ago.

Another Scarlet-Fever Serum.—Dr. G. A. Charlton of McGill University, Montreal, announces the discovery of a specific serum for the treatment of scarlatina. Of fifteen cases in which the new remedy was tried at the Montreal Civic Hospital, speedy recovery without complications is reported to have occurred in thirteen

Arrest of Hospital Physicians.—Six internes at one of the city hospitals were arrested on election day, and taken to the Yorkville court on a charge of illegal registration. The point raised in court was that they were "inmates of a public charitable institution," who, under the law, may not vote. The magistrate thought that the physicians had no right to register from the hospital as their residence, and held them in $500 each for trial. Three of them had already voted.

Negro Cocaine Fiends.—It is reported that the cocaine habit prevails to an alarming extent among the negroes in various sections of Mississippi, the use of the drug having almost supplanted the dipping of snuff among the women. In 1900 the Legislature passed an act forbidding the sale of the drug except upon a physician's prescription, but the law is ignored by nine-tenths of the druggists in the State. It is now suggested that a law should be passed making it a crime for any person to use cocaine except on a physician's certificate.

Koch Said to Be Changing Again.—A despatch to *The Sun* states that Professor Brouardel, who returned to Paris last week from attendance at the International Congress on Tuberculosis in Berlin, says that Koch no longer denies the possibility of the communication of bovine tuberculosis to human beings. Koch also admitted, he says, that milk infected with the disease might be injurious. Some time ago Professor Koch began to recede from the position taken at the London Congress, and resigned the claim of being the only discoverer and originator of the theory of the plurality of tuberculosis. To a reporter of the Paris *Figaro* he said: "The opinion which I defended at the congress in London I still adhere to. I would like to call attention to the fact, however, that I limited myself to the expression of a theory which had previously been advanced by American men of science. The public has voluntarily accorded me the privilege of parentage. But let us get down to facts: I never said that infection was impossible; all I contended was, that it could hardly have serious consequences." When he announced this theory, however, he carefully refrained from saying that it "had previously been advanced by American men of science," and it was not until Adami and others accused him of plagiarism, and he found himself opposed by nearly all scientific men, that he haltingly acknowledged that he was not the author of the theory.

An Honorary Degree for Professor Lorenz.—It is announced that the Northwestern University will confer the degree of LL.D. upon Professor Adolf Lorenz when he returns to Chicago from the West. According to the newspaper accounts, Dr. Lorenz was urged by the newly-installed president of the Northwestern University, Dr. James, to treat his daughter, suffering from congenital dislocation of the hip, but Dr. Lorenz refused on the ground that the child was too old to warrant the hope of a cure.

American Public Health Association—The thirtieth annual meeting of this association will be held at New Orleans, La., beginning December 8 and continuing five days. The Executive Committee has selected the following topics for consideration, but papers will be received upon other sanitary subjects: (1) The Pollution of Public Water Supplies; (2) The Disposal of Refuse Material; (3) Animal Diseases and Animal Food; (4) Car, Steamship, and Steamboat Sanitation; (5) Etiology of Yellow Fever; (6) Demography and Statistics in Their Sanitary Relation; (7) Cause, Prevention, Period of Incubation, and Duration of Infectious Diseases; (8) Public Health Legislation; (9) Cause and Prevention of Infant Mortality; (10) Disinfectants and Disinfection; (11) National Leper Homes; (12) Dangers to the Public Health from Illuminating and Fuel Gas; (13) Transportation of Diseased Tissue by Mail; (14) The Teaching of Hygiene and Granting of Diploma of Doctor of Public Health; (15) Sanitary Aid Societies; (16) The Relative Immunizing Value of Human and Bovine Vaccine Virus; (17) The Investigation of the Canteen System of the United States Army. The following are the officers of the association for this meeting: *President*, Dr. Henry D. Holton, Brattleboro, Vt.; *First Vice-President*, Dr. Walter Reed, Washington, D. C.; *Second Vice-President*, Dr. Jesus Chico, Guanajuato, Mex.; *Secretary*, Dr. Charles O. Probst, Columbus, O.; *Treasurer*, Dr. Frank W. Wright, New Haven, Conn.

New York State Association of Railway Surgeons.—The twelfth annual meeting of this association will be held in the hall of the New York Academy of Medicine on Thursday and Friday, November 20 and 21, at 10 A.M. and 2.30 P.M. The president of the association is Dr. H. P. Jack of Canisteo, and the secretary, Dr. George Chaffee of Brooklyn.

Reconstructing the Old Bellevue College Building.—Plans have been filed and work has begun for remodelling the interior of the old medical college building on the Bellevue Hospital grounds. The outside walls will not be touched, but the inside will be greatly changed. The two upper floors are to be made into dormitories for the employees of the hospital and will be fitted up in the most approved manner. The second floor will be taken up as a lecture hall. The first floor will contain, as in the past, a dispensary, but this also will be newly fitted out and reconstructed. On the same floor will be the hospital's offices, which are now in the main building. A special feature of the alterations will be the providing of a reception room for visitors on this floor, with an entrance on Twenty-sixth street.

The National Association for the Study of Epilepsy and Treatment and Care of Epileptics held its annual meeting on Wednesday of last week in the lecture hall of the Academy of Medicine. Two sessions were held, one in the afternoon and another in the evening. Dr. Frederick Peterson, the President of the association, in his opening address referred to the increasing interest now being taken in the welfare of the epileptic. A few years ago the 140,000 epileptics in the United States were practically outcasts, a burden to society, to their families, and to themselves. Now, in nineteen States of the Union there were provisions made for their care and treatment, and in some cases cures had been effected. In Europe also there were many homes and colonies established for the care of these unfortunates, and the movement had even extended to Asia and South America. He spoke of the work of the association, the aims of which, he said, were to promote the general welfare of sufferers from epilepsy, to stimulate the study of the causes and the methods of cure of the disease; to advocate the care of epileptics in institutions, so that they might receive an education, acquire trades, and have good medical treatment, and to assist the various States in America to make proper provision for sufferers from this malady. He appealed for financial aid and moral support of the association by both physicians and the general public. Dr. Edgar J. Spratling read a paper on "The Legal and Social Standing of the Epileptic." He held that an epileptic who commits a crime should be deprived of liberty while the disease continued, but he should not have the stamp of the convict put upon him. Dr. Abraham Jacobi presented a communication on "The Causes and Remedies of Epilepsy," and Dr. Roswell Park one on "The Surgical Treatment of Epilepsy." The latter speaker said surgical measures were sometimes of undoubted service, but he deprecated an indiscriminate resort to operative procedures. Dr. Wm. P. Spratling reported upon the work of the Craig Colony for Epileptics at Sonyea, N. Y., and several other papers were read. The election of officers for the coming year resulted in the choice of the following: *President*, Dr. Wharton Sinkler of Philadelphia; *Vice-President*, Dr. William Osler of Baltimore; *Treasurer*, Dr. William P. Spratling.

Throat Department of the New York Eye and Ear Infirmary.—The statement was made recently by Mr. John Harsen Rhoades, one of the directors of the New York Eye and Ear Infirmary, that the board was seriously considering the advisability of abolishing the throat department in the infirmary. The reason given for this contemplated action was that the great increase of the number of eye patients during the past year had taxed the resources of the institution to the utmost and it would be necessary to retrench by cutting off a branch of work which was regarded as somewhat outside the actual purpose for which the infirmary was established. This statement has called forth a vigorous protest from the friends of the throat department, who contend that the work there done is as extensive and as fruitful in good results as that in either the eye or the ear department. The number of throat patients treated annually is about ten thousand.

Gerhardt's Successor.—Dr. F. Kraus, professor of special pathology and therapeutics and director of the clinic for internal diseases at the University of Graz, has been called to the chair of clinical medicine at the University of Berlin, made vacant by the recent death of Prof. Gerhardt. Prof. Kraus was born March 31, 1858, and has been professor at Graz for eight years, having been called there from Vienna in 1894.

Contagious Diseases Barred from Colorado Railroads.—A rule has been adopted by railroad officials in Colorado that, after December 1, invalids boarding a train anywhere in the State must be able to show a physician's certificate that they are not suffering from any contagious disease.

In Favor of the Army Canteen.—Forecasts of the annual report of the Secretary of War state that he will urge upon Congress the reestablishment of the army canteen. We hope, in the interests of temperance and morality, that his recommendations to this effect will be favorably acted upon.

Dr. Pearce Bailey has been appointed consulting neurologist to Roosevelt Hospital.

Dr. George Taylor Stewart, Superintendent of Bellevue Hospital, has tendered his resignatin, the same to take effect January 1. Dr. Stewart has been connected with the hospital thirteen years.

Fourteenth International Medical Congress.—As it is expected that Madrid will be crowded during the congress week, those who are to attend the congress are advised to apply for rooms as soon as possible to the Bureau des Logements, Faculté de Médecine, Madrid. Blank forms for these applications may be obtained on request from the Secretary of the American Committee, Dr. J. H. Huddleston, 126 W. Eighty-fifth street, New York City. The Spanish Committee of Entertainment announces that the daily charge per person for lodging, service, light, and three meals is in hotels from thirteen to thirty-five pesetas and in private houses from nine to twenty-two pesetas. These sums include transportation from the station to the lodging and from the lodging to the station. The French and Spanish railroads have granted delegates a general reduction of 50 per cent. on the fares. In the United States the Trans-Continental Passenger Association advises delegates to use the regular nine months' rate from Pacific points to Missouri River points. The Spanish Transatlantic Line from New York to Cadiz and Barcelona grants a reduction of 33 per cent. on the ordinary rates for members of the congress. Subscriptions (thirty pesetas) must be paid before the opening of the congress to the General Secretary, and members should state the section or sections to which they wish to belong. The subscription for the wives of members is fixed at twelve pesetas.

An excursion for members of the congress and their families is being arranged. The trip from New York and return will require about one month. Physicians and members of their families who join this party will be entitled to the special rate of $263.00 for the round trip, including first-class passage on the steamer and railway, hotel accommodations for fourteen days in Spain, including room, meals, all handling of baggage, special interpreter, and fees. The trip will be via Gibraltar, Cordova, to Madrid. Side trips to interesting parts of Spain can be arranged, and also returns by other routes, so as to enable those who so desire to visit other parts of the continent. Physicians living in the Eastern and Middle States, seeking information concerning this party with a view of joining it, can communicate with Dr. Ramon Guitéras, 75 West Fifty-fifth street, New York City. Those in the west can obtain information from Dr. Charles Wood Fasset, St. Joseph, Mo.

Jefferson Medical College.—Dr. Addinell Hewson, for many years demonstrator, has been elected Assistant Professor of Anatomy. Dr. S. Solis-Cohen, for many years lecturer, has been elected Senior Assistant Professor of Medicine, and Drs. Thos. G. Ashton and Julius L. Salinger, for many years demonstrators, have been elected Assistant Professors of Medicine.

Dinner to Drs. Keen and Wood.—A dinner to Drs. W. W. Keen and Horatio C. Wood was given at Philadelphia on November 6 to celebrate the safe return of both gentlemen from a tour of the world covering more than a year. There were nearly 140 guests, including visitors from New York, Baltimore and Boston. Dr. John H. Musser acted as toastmaster, and toasts were responded to as follows: "Medicine," by Dr. Wm. H. Welch of Baltimore; "Surgery," by Dr. Wm. B. Coley of New York; "The Pupil in Surgery," by Dr. J. Chalmers DaCosta, who made the presentation of a silver loving cup to Dr. Keen; and "The Pupil in Medicine," by Dr. Hobart A. Hare, who made the presentation of a silver loving cup to Dr. Wood. Appropriate responses were made by Drs. Keen and Wood, and remarks were made further by Drs. S. Weir Mitchell and J. Collins Warren.

Typhoid Fever is again unduly prevalent in Philadelphia, 124 cases having been reported to the Bureau of Health for the week ended November 8 and 107 for the preceding week. There were reported also for the two weeks 83 and 74 cases respectively of scarlet fever and 36 and 57 cases respectively of diphtheria.

Medical Society of the Missouri Valley—This society held an interesting meeting at Sioux City on September 18. A number of good papers were presented, and at the close of the session the members were given a banquet at the Garrettson by the local profession. The officers elected for the ensuing year are as follows: *President*, Dr. J. M. Barstow, Council Bluffs; *First Vice-President*, Dr. Mary Strong, Omaha; *Second Vice-President*, Dr. R. E. Conniff, Sioux City; *Treasurer*, Dr. Donald Macrae, Council Bluffs; *Secretary* Dr. Chas. Wood Fassett, St. Joseph. The selection of the next place of meeting was left to the President and Secretary, and will be announced later.

Obituary Notes.—Dr. E. G. CARLETON died suddenly at Morenci, Ariz., on October 20, at the age of thirty-seven years. He was born in India, and was graduated in arts from Amherst College in 1889. He received the degree of M. D. at the College of Physicians and Surgeons in this city in 1892, and served on the house staff at Gouverneur Hospital and later at the Lying-in Hospital. He settled first in Bisbee, removing subsequently to Morenci.

Dr. G. L. COOK, formerly of Cleveland, died on November 2 in the New York Hospital from morphine poisoning. He was seventy-eight years of age, and had retired from practice.

Dr. ROBERT C. KEDZIE, professor emeritus of chemistry at the Michigan Agricultural College, died November 6, at the age of seventy-nine years. Prof. Kedzie was a native of New York State. He was graduated from Oberlin College in 1846, and was a member of the first graduating class of the medical department of the University of Michigan at Ann Arbor in 1851. During the civil war he was surgeon of the Twelfth Michigan Infantry. He filled the chair of chemistry at the Agricultural College for forty years and was retired from active service last June.

Dr. HENRY M. COX died at his home in Washington, Warren Co., N. J., on November 7, at the age of sixty-five years. The cause of his death was cancer of the stomach. He was a graduate of the medical department of the University of Michigan in the class of 1868.

DR. WILMOT AYRES died at Harrisburg, Pa., on November 7, at the age of fifty-four years. He was a member of the 127th Pennsylvania Volunteers during the Civil War. Some time after the close of the war he began the study of medicine and was graduated from the Baltimore Medical College in the class of 1883.

DR. RANSOM R. CROTHERS died at his home near Colora, Cecil Co., Md., on November 8, at the age of fifty-seven years. He was a graduate of the University of Maryland School of Medicine in 1873, and subsequently also of the Bellevue Hospital Medical College.

Diagnostic and Therapeutic Measures Overlooked by the General Practitioner in Diseases of the Stomach.—W. P. Harbin says that every general practitioner can make a diagnosis of gastroptosis by the splashing sounds. By palpation he can recognize a nephroptosis, and greatly relieve both conditions by an abdominal belt. One-half of all the digestive disturbances are attended with hyperacidity. We cannot diagnose hyperacidity with certainty, except by a test breakfast. Lavage in mornings before breakfast with calcined magnesia relieves the pain and discomfort of hyperacidity. The intragastric application of the farradic current gives strength to the involuntary muscles of the digestive tract and the voluntary muscles of the abdominal wall. The physician and the gynecologist too often consider gastric symptoms as a reflex disturbance of diseased female generative organs.—*The Alabama Medical Journal.*

A Case of Early and Continued Menstruation.—George Wells reports the case of a little girl, now seven years of age, who has menstruated regularly (nearly every twenty-eight days) since she was eighteen months old. When her mother first consulted him, he made a careful and thorough examination, and although the discharge had the characteristic periodicity of the menstrual flow, the tender age of the child at first led him to believe that it was due to other causes high up in the vagina. But, failing to discover the cause, he has held her under close observation from that time to the present, and as the bloody discharge has occurred monthly throughout this period of six years, and as the child, although not robust, shows indisputable evidence of having reached puberty—the mons veneris and the labia majora being thinly covered with long hairs, the mammæ as well developed as in the majority of adult women, the areola being well defined, and the facial expression thoughtful and matured—he has reached the irresistible conclusion that it is a case of precocious menstruation.—*Maryland Medical Journal.*

Correspondence.

CHOLERA IN THE PHILIPPINES.

(From Our Special Correspondent in Manila.)

MANILA, P. I., September 30, 1902.

THE great sanitary problem in the Philippines at the present time, of course, relates to the prevalence of cholera, and it is one which is giving much anxiety to the sanitary authorities. Persons in the United States can have no idea of the death and devastation caused by this disease; and even in Manila, outside of a few officials, the extent of its ravages through the interior districts is not fully appreciated. While up to this date more than 30,000 deaths have been officially reported to the health authorities as having been due to cholera, this number probably does not represent much more than half the deaths resulting from this disease. In many instances, the nature of the earlier cases of cholera, as it spread from town to town, was not recognized, and a proper diagnosis was not made until the disease had established itself in epidemic form. Such earlier cases were regarded by the natives as acute diarrhœas, dysentery, or gastritis of an unusually fatal type, and do not figure in the cholera returns. In many instances, cases sickened and died without medical attention, or before coming under the notice of those qualified to make a proper diagnosis. Physicians in the Philippines are few and far between, and the professional qualifications of many of the native practitioners are of a very low order. Even in the larger towns the number of physicians is totally inadequate to render proper medical care to the population under ordinary conditions, while the smaller country towns or barrios are almost universally unprovided with physicians. Districts containing a population of several hundred thousand might have only three or four medical men within their limits, and those located in the larger towns. In one city of some considerable importance, with a population of about 25,000, there was only one civilian doctor, and he was also the only one in the entire province. With deaths from cholera occurring in the above-mentioned town at the rate of fifty or sixty a day for some weeks, it is obvious that the sick and dying of the country districts round about could scarcely receive any of his attention. The army surgeons at the various military stations gave every assistance at the outbreak of the disease, but they were handicapped from the outset by not knowing the native languages and by being regarded with more or less distrust by the natives. The stringent measures which they proposed, by which alone the spread of the disease could have, perhaps, been checked, also aroused the antagonism of the easy-going, fatalistic Filipinos, who were being taught by the friars that the epidemic was a visitation of God, not to be averted by mortal means, and that the sanitary precautions of the Americans were not only unnecessary, but were made needlessly severe for the purpose of oppressing a conquered people. Because of the complaint and antagonism thus resulting, the matter was soon after taken, by the civil authorities, entirely out of the hands of the military, and the army surgeons were practically confined in their efforts to keeping the disease out of the commands with which they were serving. The latter, it may be remarked, was not an easy task, with a generally infected native population living in immediate proximity to the barracks, and often in necessarily close relations with the troops. A third reason why many cases of cholera do not figure in the returns for that disease is due to the fact that the cause of death was deliberately misrepresented by the natives, and that many cases died and were secretly buried, because of the discomfort, annoyance, restriction, and possible destruction of property, which, at least in the earlier period of the outbreak, would have resulted from the true facts becoming known to the authorities. Many cases of the disease ending in recovery were undoubtedly never reported, and these, and particularly the mild ambulant cases of choleraic diarrhœa, were probably the most potent factors in the spread of the disease. For these reasons, not only are the statistics misleading as to the severity of the epidemic, but the percentage of mortality given by them is unquestionably much too high. Throughout the epidemic in the northern islands, the official returns placed the deaths at about 85 per cent. of the reported cases. It was a general rule, however, that only the more severe cases came to official notice. The mortality in hospitals was extremely high, but the class of cases admitted was of the most severe type, the patients were weakened by transportation, and many of them were moribund at the time of admission. It is fair to consider, however, that more than one-half of the cases presenting well-marked cholera resulted fatally. Although the type of the disease, while the epidemic was at its height, was about the same over the entire islands, its prevalence varied greatly with the community. Manila, with its piped water supply of comparative purity, had a relatively small number of cases in proportion to its population. In the little country villages, where the water supply was drawn from a few wells or stagnant pools, which early became infected the mortality was very great, and the terrorized survivors, scattered in all directions, carrying the disease to other communities. In the northern districts whole villages were thus decimated and deserted, and the resulting suffering was very great. The putting in of the crops, particularly the rice-planting, was greatly interfered with, and this cutting down of the food supply, with a population living from hand to mouth and unprovided with proper means of communication and transportation, can scarcely fail to have an appreciable effect in increasing the death rate in the future, after cholera itself shall have disappeared. During the height of the epidemic, the combination of sickness and death, suffering and sorrow, seen on all sides, was very depressing. In some entire villages scarcely a family escaped, and all day the hearses and bullock carts were carrying out the dead for burial, in coffins, or wrapped in mats and banana leaves.

In some instances, the number of dead was too great for proper burial, and the stench from many shallow graves, washed by tropical rainstorms, was perceptible at long distances. Such graves attracted and furnished breeding places for swarms of flies, which undoubtedly played an important part in the further dissemination of the cholera bacilli. So severe was the epidemic in some instances, and so paralyzed were the energies of some communities, that the proper disposal of the dead was at times impossible. Efforts were at first generally made to cremate the dead, but dry wood was scarce and petroleum either could not be obtained or funds were not available for its purchase. Burial in lime was enjoined, but a sufficient supply to meet the needs of such a wholesale mortality could not be had. Even deep burial, during the rainy season of the tropics, could not be accomplished, except with great difficulty. In some cases corpses were simply tumbled over the cemetery walls, in order that they might at least lie on consecrated ground; in some of the worst-scourged communities many were thrown out into the yards and roads, and were devoured by vagrant dogs and the omnipresent swine. While family ties are very close among the Filipinos, demoralization and overtaxation of their powers rendered them callous to the presence of death and gruesome sights.

To one unacquainted with social and racial conditions as they exist in the Philippines, the question naturally arises as to why the present cholera epidemic was not prevented, or at least controlled and deprived of much of its terrors. In the great Philippine cholera epidemic of 1882 the nature of the disease was unknown, and sanitary defence had to be conducted blindly along empirical lines. Since that time, however, sanitary science had attained exact knowledge as to the specific cause of the disease, and the best methods of preventing its development and spread. In view of these facts, is there any valid excuse for the present epidemic having entirely escaped from control and having become even more severe than its predecessor under the more lax and less intelligent Spanish administration of two decades ago? Is there any reason why the American administration in the Philippines could not have stamped out cholera in the islands, as the American administration in Cuba destroyed the yellow-fever infection from its large cities? The sanitarian should not decide in the negative as to these questions, without considering the special conditions involved, and concerning which no person who is not personally acquainted with matters in the Philippines is qualified to give a decisive answer. Beyond a doubt, the sanitary authorities in the islands have made mistakes, but there is also no doubt but that the general plan of campaign against cholera was excellent, and that its failure to succeed—for it unquestionably has failed—was due largely to circumstances beyond its control, and to such conditions as do not arise to hamper the efforts of health officers in more civilized and intelligent communities. What these special difficulties were will be subsequently considered.

There is no doubt but that there was a certain time in the history of the outbreak when the infection could have been utterly destroyed and the epidemic prevented. This opportunity occurred at the time the first few cases appeared in the Farola district of Manila, a district inhabitated by low-class natives, living amid surroundings which were, exceptionally insanitary, even for Filipinos. Immediately on the diagnosis of the first cases being confirmed bacteriologically, this district should have been placed under martial law, troops should have surrounded it, and a sanitary cordon should have been established, nobody being permitted to pass in or out, before the fact of the existence of cholera in Manila was published.

The inhabitants of this district should have been removed *en masse* to the isolation camp, already prepared in connection with the outbreak of plague, and the entire district should have been burned over and disinfected. If the extension of the disease from the first foci of infection could have been prevented at all, it could have been prevented in this manner, for the first cases were but few, and the infection was undoubtedly not water-borne, but derived from the use of vegetables, thrown overboard from a vessel arrived from an infected Chinese port, and subsequently picked up and used by a few fishermen and boatmen. Unfortunately, such sanitary measures, as outlined above, if considered at all, were regarded as too drastic, and the favorable moment was lost. The news of the existence of the disease was published, and the inhabitants of the Farola, dreading curtailment of their liberty, scattered in all directions, carrying the infection with them. The sanitary guards over the infected houses were largely native policemen, ignorant of the gravity of the situation, and not proof against cajolery and bribery. It was no wonder that numerous foci of the disease were, in consequence, soon developed in other parts of Manila and in the surrounding country. When the authorities finally burned the Farola district, a week later, the harm was done, and it was another instance of locking the stable after the horse was stolen.

With the appearance of the disease in mild epidemic form, excellent sanitary rules were formulated by the sanitary authorities, and evaded as much as possible by the natives, which they were designed to benefit. Regarding the epidemic as divine retribution for sins, in which belief they were encouraged by the friars, the Filipinos considered human efforts at control, as practised by the Americans, as both useless and impious. Totally ignorant of the nature and methods of spread of the disease, they resented any restriction of their liberties and privileges. As far as they were themselves concerned, they preferred to trust to the efficacy of religious processions, much praying, the painting of crosses on their doors, and the hanging of paper crosses in their windows. The low-class natives also tied strings around their ankles and knees, with the idea that in this way they prevented the cholera virus from rising from the ground into the system. In the small country towns, during the height of the epidemic, the whole population apparently spent the time from sunset to sunrise in pounding on tin cans or bamboo, in the belief that in this way the evil spirits causing the epidemic could be driven away. Nearly all wore charms and amulets. For a while the family of every cholera patient in Manila, and others who had come into contact with the disease, were promptly placed in a detention camp for five days, while the houses were being disinfected. The patients themselves were treated in the Santiago hospital, used exclusively for cholera cases. It is said that of the 10,000 people confined in the detention camp, during its existence, cholera developed in only four or five cases—thus illustrating the value of strict segregation under sanitary conditions, and furnishing evidence of the fact that in Manila, at least for the first part of the epidemic, the disease was not water-borne. In fact, while the detention camp was in operation, the natives so isolated were much less liable to be attacked by the disease than those living their ordinary lives in the native districts of Manila. The Filipinos, however, strenuously objected to isolation of this sort, and later on, in many instances, prominent natives, in whose families the disease occurred, were allowed to be quarantined in their own houses under native—and unquestionably venial—guards. After some five or six weeks the detention camp was abolished, and there were not wanting critics who said that the civil government was more or less swayed by political motives, and was more anxious to promote good feeling among the natives than to control the disease through rigorous repressive measures. Quarantine, both local and municipal, was, of course, proclaimed, but could not be properly enforced. The guards were insufficient and untrustworthy, and after the fact of the existence of the disease was well established, the natives slipped away at night, in large numbers, through the rice paddies and plantations around Manila, and scattered the germs of the disease broadcast through the surrounding country, whence Manila was again reinfected through the medium of the food supply, upon which it depended from day to day. The absolute worthlessness of any system of land quarantine, when attempted through the agency of the Filipinos, was thoroughly demonstrated. It would probably not have been practicable to use United States troops for this purpose, except in the case of the original outbreak in the Farola, both from the insufficiency of their numbers and the fact that such action would probably have been distorted in the native mind into one of hostility and oppression. The political and military situation had also to be considered. The city was districted, and house-to-house inspection, by native inspectors, was practised—but these natives were unreliable, and the white supervising inspectors were not of a high class. The relatives of those attacked were very fearful of losing their liberty, and often the sanitary authorities would learn of the existence of a case of cholera and send their inspectors to the house, only to find the patient dead or abandoned to the care of some old woman, while the other members of the household had fled to parts unknown. Questioning invariably failed to gain any information as to their whereabouts from the neighbors—the ignorance of the Filipino is sublime when he does not desire to impart information—and the authorities could only accept the situation and await the development of new cases in some unexpected quarter. Boiled water was distributed gratuitously, and all were urged to boil any supply used for drinking purposes, but many natives continued to use the raw water of surface ponds and filthy esteros, and there was no way of preventing them from doing this if they chose to do so. It was urged that all food be cooked before being eaten, but fuel was costly, and the native and his ancestors had for generations eaten much of his food uncooked, and preferred it in that manner; particularly fruits, fish, and vegetables, the class of foods especially dangerous in an uncooked state during the prevalence of cholera.

The use of cooked foods might be advised, but it obviously could not be forced upon an unwilling population. Orders were given to exclude the dangerous class of vegetables from the markets, but this dangerous class formed a large part of the usual native dietary, and its exclusion from sale at once caused an increase in price of the other articles of food permitted to be sold. This increase in price, when the wages of a laborer are but ten or fifteen cents a day in American money, was severely felt, and these restrictions concerning the sale of food provoked much dissatisfaction among the natives, and caused many complaints to the authorities. The Filipinos preferred to take their chances of dying with cholera to having their food supply interfered with, and later, especially when funds began to run low and foci of the disease seemed to be everywhere, food inspections were to a considerable extent discontinued, and the regulation of its sale became largely a dead letter. A general cleaning up of the city was ordered and carried out, but no permanent improvement could be expected in the native districts, totally unsewered, and situated on low-lying ground, converted into a filthy bog during the rainy season. The native houses, raised on piles, stood over pools of filthy and putrid water, which in many cases could not be drained away because of the flat nature of the ground, except as a heavy rain caused them to overflow their contents into the nearest estero; in these family clothing was washed, and, in many instances, from them the supply for drinking purposes was drawn. In the mud and water underneath the house, the hogs and chickens had their abode, and into this place the garbage and refuse was thrown. Few native nipa houses had any provision for the disposal of excreta, the ordinary method being to void the excrement through a hole in the floor onto the ground below, where a hog could always be found waiting expectantly for the privilege of acting as scavenger. The bucket system of disposal of excreta was introduced in the unsewered districts of Manila, the rainy season rendering the use of dry-earth closets impossible, but its use could not always be enforced—and many of the natives preferred not to depart from the time-honored customs of their fathers, and deprive the family hog of its perquisites. Sanitary derelictions of this kind were hard to detect and still harder to punish, for the average Filipino prefers lying to telling the truth, even under normal conditions, and a cloud of witnesses could always be found to swear to anything that would be to the advantage of a friend or neighbor. They might very likely want him to perjure himself in their behalf some day—and at any rate it was always the proper thing to consistently oppose anything the Americans were trying to do. For a while such excreta buckets as were used were collected and their contents towed out to sea and dumped. With the shortage of funds, however, it became impossible to pay the excessive charges made for towage, from lack of sea transportation, and the contents of the buckets were piled up on the shore, to become a nuisance and a menace to the neighborhood. This deficiency of funds was so serious as to cripple the sanitary administration and to render many well-planned efforts of no value. Of course, when cholera appeared in Manila, much shipping and trade were diverted to the southern ports, which remained uninfected until September, and the customs' receipts in Manila were proportionately cut down, just at the time when extraordinary expenditures were required. This shortage of funds hampered every sanitary effort, and as it existed in Manila, the chief port of entry for the islands, so it existed in even much greater degree in the country villages, with little or no produce beyond that required by the daily wants of the poverty-stricken inhabitants, and no customs receipts to depend upon. If it was found impossible to control the cholera situation in Manila, with its well-organized sanitary board, after the dissemination of the infection outside the Farola district, it was obviously not to be expected that any satisfactory results could be obtained, in a sanitary way, from the smaller towns and country villages, many without a physician or even a white person within their limits. Here the sanitary administration was entirely in the control of the native presidentes, who either attempted no sanitary regulation and reforms, or else carried them out in such an indifferent, unintelligent, or ill-advised way as to defeat their purpose and provoke resentment from those for whose benefit they were intended.

The time-honored insanitary habits of the natives could not be broken up except by the constant exercise of superior force, and the imposition of just punishment for all sanitary delinquencies. Such punishment was not given; some offenders escaped entirely, others received totally inadequate punishment for severe infractions, while others were given, at the hands of the native judges, sentences which were far too severe for the minor sanitary delinquencies involved. Such punishments, instead of awakening the people to a clearer sense of the necessity of carrying out thorough sanitary measures, served to breed feelings of discontent and irritation, particularly since the cholera situation became steadily worse and worse, in spite of the regulations of the Americans. Orders and manifestoes the Filipinos were accustomed to under Spanish rule, but under Spanish rule it was never expected that such orders were to be obeyed in detail and in the spirit in which they were promulgated. Malay nature and centuries of oppression required that regulations emanating from the dominant authority should be met by secret evasion, neglect, and passive opposition. There is no question but that this attitude received the tacit encouragement of many of the poorly-educated, native physicians, and that it was supported by the friars, always antagonistic to anything American, and constantly inculcating their doctrines of the supernatural origin of epidemic disease. Even in Manila, at a mass meeting of the native physicians, resolutions were adopted condemning quarantine, isolation, and many of the sanitary regulations proposed by the Board of Health; the proposed method of treatment of the disease, along modern rational and scientific lines, was objected to with vehemence, and the meeting endorsed and urged the use of a proprietary "cure" for the disease devised by one of their number. What little the American authorities have been able to do was thus practically accomplished, despite insufficient funds, the non-support of the natives, and in the face of the political necessity that the latter should not be too greatly antagonized. Under such conditions it was inevitable that the measures taken to control the epidemic, after it was once started, would prove inefficient.

With regard to the means by which the infective agent was spread, it would seem that infected food and water, transmission by flies and by personal contact, all played their parts. Cases of cholera occurred on vessels in which the infection was directly traceable to the use of fruits and vegetables purchased from native boatmen. In Manila large numbers of cases were apparently due to infected food, and a number of whites attacked had previously patronized Filipino and Chinese restaurants. Among the whites who contracted the disease, nearly all were of the low class which consorted with the natives, and had adopted their diet and insanitary habits of living. The water supply was at fault in probably the great majority of cases, particularly in the smaller villages where the common supply was derived from a few wells or pools, which early became infected. In Manila, on the contrary, the disease did not appear to be water-borne to any extent, although some 20,000 natives lived in their insanitary way on the watershed of the Mariquina river, from which the municipal supply is drawn and piped into the city. Undoubted cases of cholera occurred among the inhabitants of this watershed, but they were relatively few, and the cases never even approximately approached in numbers to the dignity of an epidemic. A few cases occurred also among the United States troops detailed to patrol the river and prevent its infection, but there was no general epidemic outbreak in Manila, such as occurred in Hamburg, as a result of the infection of its water supply in 1892. After heavy rains, which washed much surface material into the Mariquina river, a slight increase in the number of cases in Manila, was, indeed, noted, but this increase was small, and not at all what might have been anticipated if the water supply had become virulently infected. Except at the beginning of the rainy season, no very great difference in the daily number of cases occurring in the city was noted. There is no great amount of water stored in connection with the Manila [illegible] it is practically taken from the swift current of the [illegible] and carried rapidly down to the city. It [illegible] the lack of storage, with its quiet water, interfered [illegible] not only the multiplication but also the vitality of the cholera bacillus. Flies in all probability served as carriers of the infection in many instances, particularly in [illegible], and in the later infection of other members of families when the discharges of the members first attacked were thrown out on the ground without disinfection. Personal contact between the sick and the well also played [illegible] part in the transmission of the infection, particularly since the one-room nipa shack of the Filipino [illegible] native permits of no isolation of the affected from the rest of the family, and nearly all those who attended to the needs of the sick were ignorant of the necessity for and the methods of accomplishing disinfection. Where disinfection was intelligently and systematically carried out, as at the cholera hospital in Manila, its value was most clearly demonstrated. With over 1,500 cases of cholera treated, not a single case of the disease occurred among the attendants, except in the instance of one Chinaman. As this man had only been in the hospital about [illegible] hours before seizure, it was believed that his infection was contracted outside the institution. Where disinfection was attempted by the average native, it was largely carried out in such an inefficient way as to preclude the attainment of the object desired, even where an abundance of disinfecting agents could be obtained. Later in the epidemic these disinfectants became exhausted, and further supplies unattainable, in many of the towns. A little lime, usually air-slacked and inert, might be sprinkled on the corpse and coffin, but even this attempt at disinfection was not often practicable. Bodies were buried when land was obtainable, but this method of disposal was repugnant to the natives from personal and religious motives. At the outset of the epidemic, many nipa houses in which the disease had occurred were destroyed by fire, but the distress and complaints of the people thus deprived of their homes and property soon brought about a discontinuance of this practice, under orders from the civil government, particularly as funds were not available to make good the loss for property thus destroyed. To disinfect a house with bamboo floors and walls and nipa thatch roof, by ordinary chemical means, even if the means and purpose were at hand for its accomplishment, would necessarily be a most difficult task. Fortunately, this was probably accomplished in no great length of time by the sun's rays and drying air currents. The problem was simplified by the fact that the average Filipino possesses almost no furniture, certainly none that would for long retain the cholera infection, and that he usually has his entire wardrobe on his back. Infected ponds and watercourses were mechanically cleansed by daily flushing from the torrential tropical rains, and infectious material was washed away from the vicinity of houses, through the same agency.

An interesting feature of the epidemic had to do with racial susceptibility to cholera, Filipinos being much more liable to the disease than Americans, and the latter being proportionately more affected than the Chinese. The last, in spite of their filthy personal habits, were safeguarded against cholera to a large extent, through their use of boiled water as a beverage in tea, and their preference for cooked over uncooked foods. The disease occurred among Americans almost wholly in that low class which had adopted Malay standards of living. Few of the better class of Americans, who lived up to proper sanitary standards, contracted cholera. When they were attacked by the disease, it was usually due not so much to carelessness on their own part as to circumstances over which they had no control, or to unfaithfulness of those in whose integrity they trusted. As an instance of the latter may be mentioned the case of an officer, personally most careful in matters of hygiene, who sent his native boy out to fill his canteen with boiled water. The supply of the latter was at some distance, and, as was afterward learned, the boy filled the canteen from an infected river. [illegible] drank from the canteen, and was dead from cholera the same day. Against such faults on the part of untrustworthy native servants there could of course be no absolute protection. With respect to the cases occurring among troops, these could, in almost every instance, be traced to wilful disregard of sanitary orders, [illegible] the principles of common sense. They occurred almost entirely among men who associated with the natives, [illegible] their food and drank water from forbidden sources. Disobedience of orders and indiscretions of this sort could be shown to have existed in nearly all the cases in which the disease occurred among troops.

As was to be expected, the disease spread from Manila along the most frequented lines of travel, usually extending gradually from one village to the next. Occasionally a town or district would appear to be passed over for a time, but sooner or later the disease would return and work its ravages. In its progress it almost resembled a prairie fire, at first burning furiously, then dying down, and ultimately becoming extinguished. Even in villages in which there was practically no effort to check its spread, the disease became less prevalent, and ultimately disappeared. The decrease and disappearance may have been due to several causes. Meteorological conditions undoubtedly played a prominent part, the relative importance of which has not been and cannot be determined. It is certain, however, that with the establishment of the rains the disease decreased in prevalence; perhaps by a mechanical washing away of the bacteria, but more probably by creating an environment which either resulted in their destruction or an attenuation of their pathogenicity. The rains also furnished an abundant supply of pure drinking water, which the natives used, since it was easier to put an earthenware jar under the eaves of the house than to carry that same jar to a greater or lesser distance to be filled from some permanent source of supply of doubtful purity. Another reason for the decrease of the disease was the decrease of susceptible individuals with the progress of the epidemic, for the present outbreak has at least thoroughly demonstrated that in the Philippines only a certain proportion of the population of any community are capable of contracting cholera at any given time. Many instances could be given in which a large number of people used an infected water supply and only a relatively small proportion contracted the disease, though all were equally exposed to the infection. All these factors combined to produce self-limitation of the present cholera epidemic, which has died out, in many places purely from natural causes, not in any way aided by artificial means of restriction and control. As it has died out in one place it has made its appearance in another, and thus, at the present time, we have the spectacle of the epidemic practically at an end in the northern islands, and just beginning its ravages in the southern islands, into which the disease has only lately forced an entrance.

Previous epidemics of cholera in the Philippines have ceased with the rainy season and never lasted from one dry season to another. The epidemic of 1882 is said to have been brought to an abrupt ending by two severe typhoons, almost as if the infection were washed away by the deluges of water which accompanied these storms. Judging from the past, it is therefore fair to expect that the present epidemic will have run its course by about the end of the present year, and that the islands at that time will have been again freed from the cholera infection. As already said, in the bringing about of this result, human efforts have played so small a part as to be scarcely worth considering.

As to treatment, about every drug or combination of drugs has probably been tried. Cases range from the mild ambulant cases, presenting only trivial diarrhœal symptoms, in the relatively insusceptible, to the fulminant type, which kills its victims in three or four hours. For the one class no cure is required, as the patients recover either with or without treatment; for the last class no treatment is of the least avail, as those attacked are overwhelmed by the toxæmia in such a brief space of time that any medication would have no fair opportunity to demonstrate its virtues. Any case seen, treated, and put to bed in the early diarrhœal stages, before the actual choleraic symptoms develop, stands an excellent chance to recover. *Per contra*, the chances are much against the individual who keeps his feet until the characteristic symptoms of the disease develop. The vital resistance of the individual, as modified by physical exhaustion or by conservation of energy, has a most important influence upon the result—a fact which has been most prominent during the present epidemic. A certain class of cases, which do not progress too rapidly to a fatal termination are undoubtedly benefited by judicious treatment. Unfortunately the class which can be reached in this way is not as large as could be wished, and a very large majority of the cases among natives which came under the care of a physician were in practically a dying condition when seen. In the San tiago Cholera Hospital the mortality was said to have been reduced by improved treatment from 89 per cent. at the beginning of the epidemic in Manila to 49 per cent. toward the end of the epidemic in September. It may fairly be questioned, however, if this reduction in mortality was not more or less dependent upon a decreased virulence of the cholera infection accompanying a general subsidence in the prevalence of the disease. Certainly, many physicians through the islands were of the opinion that in the later periods of the epidemic the disease did not progress so rapidly or so uniformly toward a fatal termination as when the epidemic was first established. While an almost infinite number of remedies were proposed and used, the best authorities seem to agree that a treatment combining stimulation, efforts at intestinal antisepsis, and restoration of systemic fluids gave the best results.

As cardiac stimulants strychnine, and sometimes camphor, were used early and pushed to the physiological limit. For intestinal disinfection, salol, beta-naphthol, etc., were tried and found wanting. Guaiacol carbonate and calomel, in large and frequently repeated doses, on somewhat the lines of Woodbridge's treatment of typhoid fever, seemed to give good results in many cases. The best treatment, however, and one which was given a thorough trial, was the use of acetozone, the intestinal antiseptic lately discovered by Novy and Freer of the University of Michigan. This substance is a hyperoxide, which is said to possess forty times the germicidal power of bichloride of mercury. It is absolutely harmless, and may be taken internally in doses of 3 grains every two or three hours. Sometimes a burning sensation in the gastric region follows its use, but there is no other effect on the economy. A number of observers have found that by its use by mouth the intestinal tract can be rendered sterile, which should certainly commend it in the treatment of such a disease as cholera. It is also used in 1-1,000 solution for intestinal disinfection by high irrigation. Unfortunately for the complete success of this treatment, however, death usually occurs in severe cases of cholera as a result of profound toxæmia. Destruction of the toxin-producing bacillus is excellent, but sufficient toxin may have already been produced, and more or less absorbed, before treatment to cause ultimately the death of the patient. If some suitable chemical and physiological antidote could be discovered with which to combat the unabsorbed toxin in the intestine and that already taken into the blood, the treatment with acetozone could be made theoretically ideal. In addition to the stimulant and antiseptic treatment, it has been found of much value to attempt to keep the blood in a proper condition of fluidity, replace the losses due to evacuations from the intestinal tract and to assist the kidneys in the elimination of the toxin. This is done by large hypodermoclyses of saline solution, repeated at frequent intervals. For vomiting, ice, champagne, or carbonated water is employed. Food is withheld. The patient is, of course, kept absolutely quiet, and made to conserve his energies in every way. It must be confessed, however, that treatment is at present far from satisfactory, as must always be the case with a disease in which the transition from apparently perfect health to death may be a matter of only three or four hours. No more harrowing scenes can be imagined than those which accompany a cholera epidemic, especially as the disease is characterized by so much suffering and so little can be done for relief and recovery. To watch a score of patients carried into the wards of a cholera hospital during the day, and to see four-fifths of them carried out for burial before nightfall is an experience which will not soon be forgotten, and which most forcibly impresses the physician with the present limitations of medical science, and his helplessness in the presence of one of the greatest scourges of humanity.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HARVEIAN ORATION—THE SANITARY MEDAL—CANCER, MAMMARY AND UTERINE—OBSTETRICAL AND GYNECOLOGICAL SOCIETIES—ST. GEORGE'S HOSPITAL—GUILD OF ST. LUKE—CHURCH SANITARY ASSOCIATION.

London, October 24, 1902.

The Harveian Oration at the Royal College of Physicians was duly delivered on the 18th inst. Dr. David Ferrier, F.R.S., was the orator this year and took for his subject "The Heart and Nervous System." He passed in rapid review our present state of knowledge of the influence of the nervous system on the heart and vessels, tracing the steps by which that knowledge has been attained. The subject had attracted the attention of Harvey. Some of the earliest anatomical observations on this matter were made by Willis; some of the latest researches by two English physiologists still living The differentiation of the great system of visceral or splanchnic nerves from the somatic is the "distinguished merit of Gaskell," and we owe largely to Langley ' what is known respecting the distribution of the ultimate ramifications of this great system of nerves." The orator concluded by saying that his object had been to present a concise sketch of some of the principal relations of the heart to the nervous system, but he had to leave many problems untouched, while some of those mentioned were still hypothetical. "Doubtless," he said, "some Harveian orator of the future, if he takes up the same theme, will be able to expound it more luminously in the light of fuller and riper knowledge."

After the oration the President presented the Bissett-

Hawkins medal to Mr. W. H. Power, which is awarded to the medical practitioner who, in the judgment of the college, deserves special recognition for his work in advancing sanitary science during the preceding ten years.

Secondary deposits in one or both ovaries are found in about 10 per cent. of cases of mammary cancer. A very remarkable case of this kind was communicated to the medical society by Mr. Bland Sutton—the most remarkable he had ever seen. The case also bears on the relative frequency with which cancer attacks both breasts. In reference to this, Mr. Sutton observed that he had watched some patients in which he suspected secondary deposits and afterward found that the suspicious nodules were not cancerous. He had come to the conclusion that a woman with cancer in one breast was five times more likely to have secondary deposits in one or both ovaries than in the other breast. As to the case from which the tumor exhibited was taken, the right breast was removed in January, 1894. Recurrence in three years and again in four years—each time removed. In January, 1899, the other breast was affected and removed. For two years the patient remained well. In January of this year a tumor appeared in the abdomen and was removed in March. It was the right ovary, dense, heavy, and cancerous, seven inches in each diameter. Mr. Hutchinson, Jr., from its size and limitation to one ovary, thought it must be unique. Recurrence in the opposite breast he considered rare, and it used to be regarded as a contraindication to operation, but he had seen removal followed by successful results. Mr. Gould did not think recurrence in the opposite breast quite so rare as some, though it was certainly infrequent. Dr. V. Bell had seen a case of recurrence in second breast in which after removal the patient remained well up to date—a period of five years.

Cancer was also under discussion at the Obstetrical Society. Dr. Cuthbert Lockyer gave further particulars of a case reported last year. The patient, aged thirty-five years, had a large growth projecting from the cervix uteri. She was operated on in 1901. A month afterward there growth in the rectovaginal septum, and she died five months later. The uterus was shown; the growth extended into the internal os, but did not involve the body; it seemed to be a squamous-celled epithelioma. Dr. Rose thought no operation of use when the disease passed beyond the uterus, and the only trustworthy operation was removal of the entire uterus. Eight cases of cervical cancer which he had treated were free from recurrence from four to fifteen years. Dr. Spencer recommended removal of the cervix high up, as well as part of the body, by galvano-cautery; but it was not safe to cauterize the broad ligament. Dr. Duncan said everything depended on the extent of the disease. The great mortality was due to operating when the vaginal walls and pelvic glands were involved.

Dr. Lewers showed a specimen of cancer of the body of the uterus from a single woman aged fifty-five years. As it was impossible to remove the growth in one piece by vaginal hysterectomy, he performed pan-hysterectomy. Before opening the abdomen he passed a ligature round the internal os. Dr. Duncan and Dr. Horrocks both approved of ligaturing the os. It prevented the contents of the uterus passing downward.

Dr. Duncan showed a gravid uterus at the third month with epithelioma of the cervix. Vaginal hysterectomy was performed, and the patient, at thirty-four, did well.

Professor J. W. Taylor related a case of inversion of the uterus, which was irreducible by ordinary means. The inversion was complete, the orifices of the fallopian tubes could not be seen, there was no definite line of demarcation between the uterus and vagina. She was admitted to hospital in the last stage of anæmia from the frequent hemorrhages and vomiting, and had to be sustained by nutrient enemata. After opening the peritoneum and pushing it up reduction was still impossible. The anterior wall was, therefore, incised and the inversion reduced. The incision was sutured. A week after suppuration took place, but the patient recovered. Prof. Taylor suggested that it might have been better to cut a wedge from the uterine wall.

The treatment of this case met with little approval at the meeting. Mr. Buller-Smythe thought Aveling's repositor should have been tried, it was better than Tait's, and almost always successful. Dr. Heywood Smith suggested that intermittent squeezing of the inverted fundus, though tedious, was often effectual. Pressure emptied the vessels and caused the muscular tissue to relax. If then pressure were made with the thumb at the orifice of one of the oviducts, where the tissue was thinner, it was often easy to reduce the inversion. Dr. Handfield-Jones also discountenanced the operation. The long, weak scar in the wall would be a source of danger in a future pregnancy. The removal of the uterus would have been simpler and [illegible]. In a similar case he had found it equally difficult to keep the cup of Aveling's repositor on the uterine body, but, by packing swabs round the womb in the upper vagina and by patience, he had succeeded.

Dr. H. Spencer held that no plan equalled the use of Aveling's instrument. Pressure with it and patience would overcome the muscular resistance in nearly every case. Dr. Duncan agreed with this, and said that by the repositor and packing he had reduced an inversion of nine years' standing. Dr. Blacker thought the objection of Dr. Handfield-Jones important, as the cases usually occurred in young women in whom pregnancy might be expected.

Dr. Spencer exhibited the Porro medal, which was struck to commemorate the twenty-fifth anniversary of the first Porro operation, and presented to the society a copy of the book issued on the same occasion.

The Gynæcological Society has resumed work with its wonted vigor. Prof. Taylor showed a specimen of tubal gestation which suggested a form of rupture not hitherto described, for at one end of the sac was a congeries of large dilated vessels, apparently on the point of bursting. He also read an account of a case of uterus bicornis with rudimentary right horn. He removed this horn without tube or ovary and fixed the uterus in anteflexion. Good recovery followed.

Mr. Bowerman Jessett showed four specimens illustrating the significance of uterine hemorrhages due to tumors. One was cancerous, the others were fibroids. Mr. Jessett also read a paper on "Some Complications Arising Subsequently to Cœliotomy." He dealt with pain and intestinal or ureteral occlusion resulting from adhesions to the abdominal wound, or to the line of suture to the peritoneum in the floor of the pelvis, or to exposed stumps, or between folds of intestine or omentum. Such adhesions might reform, and he had known the abdomen to be reopened five times on account of them. To avoid them the operation should be, as far as possible, aseptic, the greatest care should be taken to cover all raw surfaces with peritoneum, and to accurately approximate the edges of the serosa. For suturing the peritoneum he uses fine catgut, also for any vessels or adhesions, but silk for the ovarian and uterine arteries. The parietal peritoneum he closes with three to six catgut sutures through the fascia and muscle; then he unites the fascia with continuous catgut, and the edges of the skin with silk or horsehair, also continuous. He emphasized the importance of getting the bowels to act within thirty-six or forty-eight hours, either by calomel or salines. Many early cases, he believed, died—not from peritonitis, as was supposed, but from tympanitis, due to paresis of the bowel, produced by the opium given to constipate for some days after operation. He regarded drainage as the chief cause of ventral hernia and so drained through the vagina. He thought it a mistake to wash out the abdomen.

At a recent meeting on behalf of St. George's Hospital it was stated that the annual expenditure is about £40,000—double what it was fifty years ago—but the income is only half that amount. Mr. Vinrace, M.R.C.S., thereupon inquired, through the *Daily Graphic*, on whose behalf this money is expended, seeing that the hospital is situated in the wealthiest part of the metropolis? He remarked that if it were for the *bona-fide* poor only no one could object; if otherwise, the inquiry promised at the meeting should extend to the means adopted to prevent hospital abuse.

Mr. Timothy Holmes, who is treasurer of the hospital as well as consulting surgeon, took up this challenge, and, in an excellent letter in the *Graphic*, explained the position. As to the the circumstances of the patients, he says the board exercises the greatest care. There are no letters for out-patients, and the great majority—about three to one—of in-patients are admitted without recommendations, solely on account of the gravity of their ailments. Mr. Holmes adds that "seeing is believing, and if Mr. Vinrace will do me the favor of meeting me at any convenient time at St. George's we will go through any of the wards he may choose, and he can judge for himself."

This straightforward way of meeting the criticisms of a medical practitioner might very advantageously be imitated by the managers of some other hospitals.

The Guild of St. Luke has scored a success. On Wednesday evening a great number of doctors attended the service at St. Paul's Cathedral in their robes. The service was intoned by a minor canon and the sermon preached by a bishop. The music was rendered by the choir of the Gregorian Association, numbering some 250 voices.

The tenth annual meeting of the Council of the Church Sanitary Association was held on Wednesday, when Dr. Collingride, Medical Officer of Health for London, presided. The annual report pointed out that the chief obstacles to sanitary reforms are ignorance, selfishness, and the difficulty of getting legislation. A resolution was unanimously adopted to the effect that teachers and preachers should inculcate the Christian obligation of endeavoring to secure for others pure air and water, abundant light, and wholesome dwellings, with good food and drink—in fact, whatever contributes to the maintenance of health.

Progress of Medical Science.

The Boston Medical and Surgical Journal, November 6, 1902.

Round Shoulders and Faulty Attitude.—Robert W. Lovett says that the indication from the study of many cases seems to be that the cure of the form of faulty attitude known as round shoulders is often accomplished by a readjustment of the whole attitude, involving the relation of legs, pelvis, and head, rather than by any marked straightening of the spine. The author gives a method of measurement and record which presents a side elevation of the whole attitude, and the relation of legs, thighs, pelvis, spine, and head to each other and to the perpendicular. The seat of faulty attitude, he says, is not as yet formulated. Gymnastic treatment should be general and local.

The Actinic Rays. Edward A. Tracy reports three cases demonstrating the use of the actinic rays in minor surgery. In the first a sebaceous cyst an inch in diameter was removed from the scalp without pain, the actinic rays being used for anæsthesia. They were applied from a No. 3 Minin's lamp, at a distance of ten inches for fifteen minutes. In the second case a subcutaneous abscess the size of a marble was removed from the thumb under actinic ray anæsthesia, and the rays were also applied afterward in place of all other antisepsis. In the third case a skin slough an inch square was removed from the palm of the hand. Finsen uses the actinic rays for the cure of lupus. Minin uses the rays in the treatment of luxation burns, hæmatoma, acute myositis, and articular rheumatism, and for the pains accompanying pleurisy, contusions, etc., and for lupus in particular.

Journal of the American Medical Association, Nov. 8, 1902

The Purse-string Suture in Gastrorrhaphy for Gunshot Wounds; an Experimental Contribution.—N. Senn says that in the treatment of gunshot wounds of the stomach the principal object of suturing should be to close the perforation in such a way as to guard securely against extravasation and at the same time approximate and hold in apposition a maximum surface of intact, healthy peritoneum. This is accomplished by making a cone of the injured part of the stomach, with the apex corresponding with the wound directed toward the lumen of the organ. The purse-string suture, applied in a manner described in the experimental part of this paper, will maintain this cone until the healing of the visceral wound has advanced sufficiently to render further mechanical support superfluous. The cone on the mucous side of the stomach acts in the manner of a valve, which in itself is an effective barrier against the escape of stomach contents, while the circular suture constitutes almost an absolute safeguard against leakage, and brings in contact the serous surfaces in the interior of the cone. For wounds of the posterior wall of the stomach Senn recommends a purse-string suture of heavy, durable catgut, to be applied through the anterior wound. The anterior wound is closed with a purse-string suture of silk, of medium size, applied to the base of the cone on the serous side. It is desirable that the circular suture should cause no necrosis of the included tissues. By using an absorbable suture in closing the posterior wound in the interior of the stomach, this object is gained, as only a small part of the thickness of the stomach wall is subjected to pressure, and the tension caused by the ligature is gradually lessened by softening of its material, and is entirely removed by the absorption and digestion of the ligature in less than three weeks Diagrams are given in the paper which illustrate the manner of passing the sutures.

Metastatic Sarcoma of the Choroid.—M. Wiener reports a case of this rare affection He was fortunate enough to be able to remove the eye and subject it to careful examination. Sarcomatous patches were visible on macroscopical examination, the largest being just below the optic nerve entrance, and apparently just including it. The patch was of oval shape, 8½ mm. long in vertical diameter by 6 mm. wide in the horizontal; it had white, lustrous, smooth appearance, clear and distinct outline, and raised above surface about 0.5 mm. Immediately above this was a circular patch 3 mm. in diameter, of the same appearance as the former in the center, but pigmented toward the circumference. Three mm. to the temporal side of this last patch was an irregular, ragged, rectangular-shaped one, 6.0 mm. long by 4 mm. wide, of reddish color (probably from choroidal pigment), in some places darker than in others. This patch, unlike the others, had an uneven, broken surface, elevated in some places to about 1 mm. Two more sarcomatous areas were visible, one just below the macula lutea, the other just to the temporal side. Both of these were whitish, with here and there deeply pigmented spots. The optic nerve seemed to be somewhat swollen behind its entrance. Microscopically, these patches were seen to be chiefly of the small round-celled type, with some spindle cells; the growth was traversed by many blood vessels and channels, and was located chiefly in the tunica vasculosa, involving, also, where it broadened out, the choriocapillaris. Here there seemed to be a special cell proliferation or accumulation from the lamina vitrea. Surrounding each patch were more than the average number of vessels, filled with blood, and some of these attaining large size. Scattered throughout the growth some choroidal pigment could be seen, having undergone degeneration or change of shape in many instances. The optic nerve was swollen and somewhat thickened at the entrance to the globe, but there was no infiltration of sarcoma cells.

Medical News, November 8, 1902.

The Use of Salicylate of Sodium in the Treatment of Pneumonia.—A. Frank Taylor speaks of Sebring's treatment of pneumonia by this drug. The writer has for nearly two years been following essentially the same plan. Out of the entire number of patients treated—twenty-five cases—he has lost but one—an infant twenty-two days old. These patients ranged in age from twenty-two days to sixty years. The writer gives to adults 15 grs. of salicylate of sodium once in four hours, and medium doses of veratrum viride and aconite combined, once in four hours until the temperature falls, then lessens the salicylate, all the time using turpentine and lard on the chest, with a covering of flannel and a rubber dam. There seldom is any necessity for opiates. A little codeine or heroin with muriate of ammonia, etc., to alleviate the cough is usually the only narcotic used.

The Etiology of Smallpox; with Special Reference to Its Microbiology and a Demonstration of Its Microbe.—William Seagrove Magill declares that an epidemic of smallpox is invariably the result of imported contagion. The specific germs are brought to a fresh locality by an individual from an infected spot, or by infected materials—rags, clothing, paper, household articles, etc. Smallpox is contagious at every stage of its existence. The diffusibility of variola is far greater than that of any other eruptive fever. Immunity from the disease may be natural or acquired. Thirty years of bacteriological investigations, some of them by the best specialists in the world, have completely failed to demonstrate any form of bacteria entitled to the slightest claims of specificity in accordance with the prescribed rules of the scientific method of research. Since the bacterial origin of smallpox has not been determined, the suggestion of a protozoic origin is being investigated. New work in the cultivation of protozoa is being done in the laboratory, but progress in this line is not yet sufficiently precise to authorize its presentation.

A Modified Method of Auscultatory Percussion.—Albert Abrams has employed his method for several years. He has often controlled its accuracy by skiascopy. It embodies the principles of transsonance. The clavicles, sternum, ribs, or vertebræ are percussed directly, without the interposition of the finger as a pleximeter. The blow is either light or strong, according to whether the superficial or deep dulness is to be elicited. In obtaining cardiac dulness, the clavicle or manubrium is percussed directly, and the stethoscope is gradually carried toward the organ in all directions from the lung. The cardiac area is at once indicated by a dull tone supplanting a resonant one. Lung-consolidation is easy to elicit by this method. If the transsonance of the apices is to be determined anteriorly, the stethoscope remains fixed first over one and then over the other apex, while immediate percussion is executed on a prominent vertebra. If the apices are to be auscultated posteriorly, the blow is limited to the manubrium. It is possible to outline the right auricle and the left ventricle on the posterior chest surface if the patient is erect, with the body inclined slightly backward. The pectoral chest-piece of the stethoscope should be of small caliber. In corpulent individuals the percussion blow is not conveyed to any distance. To outline the lower border of the stomach: With the finger, the lower ribs over the semilunar-shaped space of Traube are percussed, the stethoscope being fixed primarily in the hypochondrium, in order to detect the character of the tympanitic tone. While percussion is continued, the end of the stethoscope is gradually carried downward until the disappearance of the tone indicates that the lower border of the stomach is reached.

New York Medical Journal, November 8, 1902.

Subcutaneous Injections of White of Egg.—H. C. Jackson combats the views expressed by Southgate Leigh in a previous issue of the *Journal*, and contends that it is practically impossible to obtain sterile fluid, egg albumen, and that this proteid, introduced as such, directly into the circulation is not assimilated, and therefore can supply the body no energy. This is, therefore, an argument against its use as a hypodermic nutrient. The danger of inoculation with pathogenic organisms should alone be sufficient cause for its non-use, were it not supported by the lack of power of the body to utilize the proteid when thrown directly into the blood.

The Relationship Lues Bears to the Body Politic.—S. P. Collings reviews the history of syphilis among ancient peoples, and makes a plea for a more general instruction of the laity at the present time concerning the communicability and transmission of the disease, just as is being done in regard to tuberculosis. Special stress must be laid upon the modes of innocent transmission, and also upon the fact that those who have this disease are for several years a source of danger to those thrown into intimate contact with them, and that each infected person should have his individual effects, to be used by him and by him alone. If we are to have legalized prostitution regulated upon sanitary principles consistency requires that the men who visit legalized resorts should be subjected to the same rules and regulations as the residents of the houses.

Diseases Preceding and Following the Abuse of Alcohol.—T. D. Crothers says that in about 30 per cent. of all inebriates before the craze for alcohol and subsequent inebriety, there are incipient or well-marked forms of paresis and other disease states. Among these early disease symptoms can be traced degrees of dementia, syphilis, trauma, local inflammations, the presence of toxins and bacterial products, with reflex disturbances due to tumors and the pressure of foreign bodies on the nerves. These are not recognized, and are therefore seldom studied, as a condition of predisposing and exciting causes. Especially prominent is general paresis. Closely allied with this are the dementias. Other preceding conditions are sunstroke, blows on the head, concussion, influenza, and prolonged wasting diseases. Not infrequently tuberculosis is present, as may also be dyspepsia and nutritive disorders and rheumatism. Following the abuse of alcohol, we may have dementia, arteriosclerosis, cerebral hemorrhage, atrophic cirrhosis of the liver, peripheral neuritis, stiffness, cramps, and pains in the extremities, nephritis, gastritis, etc. In all these cases there is starvation and toxic poisoning. The direct action of alcohol on the hæmoglobin of the blood diminishes the power of conveying oxygen, and this strikes directly at the nutrition of the body. The toxins of alcohol not only destroy nutrition and increase waste matter, but diminish the elimination process. Some of the conclusions which will be apparent from this clinical study are that at least one-third of all inebriates have suffered from some disease, present before alcohol was first used.

American Medicine, November 8, 1902.

Congenital Hernia of the Liver into the Umbilical Cord, with Report of a Case.—J. W. Bullard states that this developmental deformity is very rare. The child he describes was a boy weighing three and a half pounds. In the tissues of the cord was a tumor about the size and shape of a hen's egg. The tumor was in the tissues of the upper side of the cord; it was pinkish, partly solid, and could not be reduced. There was no impulse transmitted to the tumor when the child cried, though it was a little more tense. As the child was weak, the operation was deferred. On the twelfth day the baby was not doing well and operation was decided upon for the next day. The abdominal cavity was opened immediately below the tumor, and the incision was carried up on either side of the tumor. The contents of the hernial sac were found to be composed entirely of liver, about half of which appeared to be in the sac. At the lower border of the sac the liver was not firmly adherent, and was separated from the sac walls almost to the fundus, but at all other points the adhesions were so firm that it was impossible to break them up. The abdominal wound had to be closed up on this account, and the child left to its fate. It died twenty hours later. The writer concludes that it is advisable to do the radical operation in these cases soon after birth, as delay with its changes in the cord and the amniotic coverings of the sac, is likely to lessen the chances for a favorable result.

The Oxygen Bath for the Peritoneum and Its Possible Value. Second Report on the Cancer Case Relieved by an Exploratory Laparotomy.—Eugene R. Corson reports a case of inoperable carcinoma of the breast. He decided to try the Beatson operation on the patient. There was a fair-sized uterine fibroid, with tubes and ovaries and bowels adherent to the uterus. Just as the adhesions were about to be broken up, the patient stopped breathing. She was resuscitated and the abdomen was closed. At the end of forty-eight hours marked improvement occurred, in both objective and subjective symptoms. This improvement continued for one month, and then the infiltration of the tissues of the chest returned very rapidly, together with great dyspnœa and pain and a rapid and weak pulse. The abdomen was again opened this time under cocain. Nitrous oxid was passed through a warm wash bottle to raise its temperature before it entered the abdominal cavity. The pulse and respiration became so bad that in a few minutes the peritoneum was stitched, and the rest of the wound brought together with adhesive strips. Soon the patient again improved. Fluid in the left pleural cavity was drawn off. In about eight days oxygen was again passed over the bowels, this time by means of inserting a trocar. The gas was allowed to distend the abdomen until it became large and tense. This was accomplished three times. There was general improvement again from this treatment. Twelve days later this oxygen bath was repeated, and was again followed by improvement. Four times after this, this treatment was repeated, each time, excepting the last, being followed by improvement. The patient died three months after the first opening of the abdomen. The writer suggests that if the stimulation from the oxygen is greater than that of the ordinary atmosphere, perhaps that following the use of ozonized oxygen may be greater still, and he believes the experiment worthy of trial. This case shows that there was a considerable absorption of gas by the peritoneum—rapid, as compared with that by the connective tissue spaces. He believes that in cases of pulmonary œdema and congestion, due to whatever cause, this method would give relief, and perhaps tide the patient over a dangerous moment.

Philadelphia Medical Journal, November 8, 1902.

Suppurative Tubal and Ovarian Disease.—J. J. Gurney Williams especially emphasizes the following points: Gonorrhœa is by far the most frequent cause of suppurative tubal and ovarian disease. Vaginal puncture is dangerous and unsurgical. The mass should always be removed through an abdominal incision. Plain sterile water should be used in all abdominal operations. The use of mercury, permanganate, or any antiseptic, except alcohol, is unnecessary in the preparation of the operator or assistants, as cleanliness is the great point, and may be obtained by soap, water, and brush, using many changes of water and taking many minutes to scrub. Silk should be used in all tying within the abdominal cavity. An absolute differential diagnosis previous to operation is in the majority of cases impossible. The cases in which drainage is used usually do better than those not drained. The absolute avoidance of morphine, or any form of opium, before or after operation should be observed. The objections to operations are not founded on fact, and there is not enough consensus of opinion that these suppurative conditions should always be operated upon.

Movable Kidney; Its Diagnosis and Treatment.—Robert J. Reed states that in not a few of the patients who suffer from movable kidney the symptoms are for a long time indefinite and without local manifestation. The symptoms are diversified. The digestive system is disturbed, there may be cardiac palpitation, almost constant flatulency, and many nervous disturbances. In many cases there is marked discomfort and actual pain, when the digestive and neurotic symptoms have reached an aggravated form. The severity of the pain generally depends upon the displacement as well as upon the length of time that the extreme displacement has existed. There is now and then an attack of extreme pain resembling renal or hepatic colic. Upon palpation of a movable kidney its striking and very natural characteristic is to slip away with ease under the liver into its normal position. Its smooth surface and distinct outlines are very significant. In some cases the hilus can be felt. There is a certain degree of tenderness, always much the same and possessing the peculiarity experienced by pressure upon the testicle or ovary. It is well that an early diagnosis of the condition be made. Not every case requires operative treatment. Tight clothing should be discarded, as well as skirts suspended from the girth dragging downward all of the abdominal organs by their weight. The abdominal supporter, if strong and well fitted, is helpful. In two cases under observation the straight front corset is giving fair success. A direct support to the kidney is generally necessary, and may be given by a strip of adhesive plaster and a small pad. The plaster should be three inches wide, and should reach from below the umbilicus to the middle back about the level of the tenth rib. A small pad of cheese-cloth should be placed below the margin of the ribs, at a point opposite the tenth and eleventh ribs, and be held in place by plaster. It should be applied with the expiratory act. If these measures do not afford relief, if the symptoms continue, and especially if albuminuria develops, an operation should be performed. The writer adds a few important points: Seek to avoid wounding the iliohypogastric nerve. Do not attempt to anchor the kidney in too high a position, its major portion should rest below the twelfth rib. Aim to keep the kidney in its normal relation to the axis of the body, in fastening it in its new position. Keep the patient in bed three or four weeks, and in many cases tonic and constitutional treatment should be begun and continued indefinitely. If the patient has suffered long, she should not be encouraged to feel that all of her troubles will cease after the operation. The surgeon should first make sure that there is not a general ptosis of the abdominal organs, and possible displacement of the uterus. Complications such as these which are overlooked will often explain an unsatisfactory result in the operative treatment of movable kidney.

The Lancet, November 1, 1902.

Ozone in Chronic Middle-Ear Deafness.—Four cases treated by this method are reported by G. Stoker. The ozone was generated by an electric current acting in a Ruhmkorff's coil, to which an ozonizing tube was attached. The ozone so generated was pumped through an Eustachian catheter for about three minutes from twice to four times a week. In all the cases hearing was considerably improved. In some improvement was remarkable, especially so as to the disappearance of tinnitus.

Acute Pancreatitis Associated with Cholelithiasis and Glycosuria; Cholecystotomy; Recovery.—The case is recorded by W. Gifford Nash. The patient was a fat male, aged sixty years, who had had attacks of epigastric pain extending over a period of seven years. The onset of the last attack was sudden, and the pain was in the epigastrium. There were nausea, vomiting, hiccough, and collapse. The temperature at first was subnormal, but in the course of two days it rose two or three degrees above normal. The pulse was very rapid (160). The whole abdomen became enormously swollen, and suggested intestinal obstruction. This was relieved by enemata and aperients, but quickly reappeared. Later, as the abdominal swelling subsided, there was increased resistance over the pancreas, giving the impression of effusion into the lesser peritoneal cavity. Then at the operation fat necrosis was seen and a gallstone was removed. The author believes that the stone in the gall-bladder was accompanied by an inflammation of the bile passage, and that some infection spread along the ducts of the pancreas to that viscus itself.

Some Clinical Aspects of Vaccination.—Arthur Maude speaks of recrudescence of pocks, "raspberry excrescence," character of the pock, constitutional symptoms, and the value of the areola. He believes in "absolute" vaccination—that is, the repetition of vaccination at short intervals till no reaction whatever is produced again. He has seen some cases in which recurrent attacks of boils have followed revaccination in persons not previously subject to boils. The various rashes are more common after revaccination than after primary inoculation. He has seen eruptions due to mixed infection. He has also seen one case in which possibly tuberculous disease of the humerus has followed vaccination. This patient was a man of sixty years. The local reaction was severe and protracted, as he used his arm during healing. The areola was large and, the scabs were tough and leathery, and productive of suppuration, but there was no evidence of skin tuberculosis. Some months after he complained of persistent pain on movement of the shoulder-joint, and a senile osteoarthritis was suspected. Later a tentative diagnosis was made of tuberculosis, but there was no positive evidence that this lesion was actually present.

British Medical Journal, November 1, 1902.

Functional Derangement of the Eye.—Robert Marcus Gunn speaks of the difficulty in distinguishing between an hysterical loss of sight and malingering. Malingering will probably always be a source of difficulty. Aside from cases of traumatic origin, functional cases are far more common in females. The division between hysteria and deceit is not strongly drawn. Cases in which neutralized glasses at once cure the defect, are cases of feigning undoubtedly, although cure by suggestion may be thought of. Complete double amaurosis is extremely rare. Occasionally functional amblyopia occurs in the form of homogenous hemianopia. Cases of functional amblyopia consist of two groups: Idiopathic, occuring usually in women, and sometimes in children. Traumatic, occurring probably equally in both sexes, but always in adults. As to the nature of the nervous system at the bottom of these cases, we are ignorant. It may be assumed, at least in most cases, that there is a temporary partial or complete loss of the power of conduction between the lower or middle visual centers and the highest conscions centers, and possibly the same is the case with infants who, with no obvious disease of the eye, take no notice of objects. The prognosis is good. The treatment is to remove the patient from home surroundings, avoid too much sympathy, give drugs like asafœtida, and the use of faradism.

The Cause of Heart Irregularity in Influenza, with a Demonstration of the Clinical Polygraph.—James Mackenzie states that the clinical polygraph is an adaptation of an ordinary tambour to a sphygmograph. By it, movements due to the circulation or respiration can be registered on the same tracing paper and at the same time as the radial pulse. The point of the lever of the tambour lies on the paper just above the lever of the sphygmograph. The tambour is connected by an elastic tube with a shallow open cup, "the receiver." This cup is placed over any pulsating part, and the movements are conveyed by the tube to the tambour. Tracings were taken in the case of a patient recovering from influenza. They showed evidence of a discordance in the actions of the right auricle and of the left ventricle. The movements in the veins of the neck showed from time to time the irregularity of the heart's action, for they were every now and then suddenly distended by a wave much larger than usual. This large wave always occurred at the same time as the radial pulse. By observation it could be seen in the superficial jugular veins. It obscured the movement that the carotid should have made. It occurred exactly at the time that an auricular wave was due. At the time of the occurrence of this auricular systole the ventricle had also passed into systole. The auricular contents could not be sent forward into the ventricular chamber, but were all sent back into the veins, thus causing the large wave. It can thus be inferred that the right ventricle followed the same rhythm as the left ventricle and not that of the right auricle. We so constantly associate the auricles with their ventricles, that it seems reasonable to expect that when there is discordance the two halves of the heart will act independently. The poisoning of the heart by certain drugs, as digitalis, causes a slowing of the pulse, and a discordance between the actions of the auricles and ventricles. The heart symptoms in this case, it is suggested, are due, not to vagus stimulation, but to a poison acting like digitalis directly on the heart itself.

Deutsche medicinische Wochenschrift, October 16, 1902.

Carcinomatous Inoculation Metastases.—Olshausen believes that carcinomatous metastases due to inoculation, or, more properly speaking, autoinoculation are much more frequent than is generally supposed. The author reports several cases in which, following the removal of carcinomas, recurrence took place, first developing upon the cicatricial tissue, formed as the result of the operation. In such instances the recurrent tumors must be regarded as arising from inoculation. The same is true with respect to non-malignant tumors, especially those of the ovary. Observations along this line are of significance in connection with the present widespread discussion concerning the etiology ot carcinoma.

Agglutination of the Streptococci.—Fritz Meyer has investigated this matter experimentally, and finds that streptococci, like other bacteria, are agglutinated by specific immune sera. By such an agglutination streptococci causative of anginas and pyogenic infections may be absolutely differentiated. Streptococci which are found in the anginas of scarlet fever, rheumatism, and angina simplex show gradual but not absolute differences in their agglutination capacity. All of these facts strongly confirm the opinion that the streptococci, so called, are a multiple species, and it is apparent that antistreptococcus serum, which is to be employed for therapeutic use should not be obtained by the inoculation of streptococci, the virulence of which has been increased by animal passage.

Berliner klinische Wochenschrift, October 13, 1902.

Technic of the Leucocyte Count.—Robert Breuer has devised a new cell for use in the enumeration of leucocytes. It is of the same depth as the Thoma-Zeiss, but is divided by horizontal and vertical lines into nine spaces of one square mm. each. Every square mm. is subdivided into four equal parts by three horizontal lines, in order to further facilitate the counting. In making the count the blood is diluted one to ten, and a drop placed in the cell as in the use of the ordinary Thoma-Zeiss apparatus. The leucocytes in five of the square mm. are then counted, and the result obtained multiplied by twenty, which gives the final figures, viz., the number of leucocytes in one c.mm. of the undiluted blood. If it is desired to make a differential count at the same time, Türks or Zollikofer's fluid may be used as a dilutant, and a differentiation between the mono- and polynuclears thus obtained. The advantages of this cell are greater accuracy and simpler computation than is possible in the use of the Thoma-Zeiss.

Berliner klinische Wochenschrift, October 20, 1902.

Causes of Primary Glaucoma.—Georg Levinsohn says that an increase of connective tissue in the ciliary body is the cause of primary glaucoma in the vast majority of instances. This increase leads to an enlargement of the ciliary body, and a deviation from its normal position and relations, so that the iris assumes a concave shape with the concavity backward. This produces a lessening of the size of the anterior chamber, and a more or less marked obliteration of Fontana's space. The abnormal position of the iris also gives rise to a dilatation of the pupil, which still further assists in the blocking up of the canal of Schlemm. Specimens are submitted in support of this theory. Furthermore, it corresponds with the well-known fact that an early peripheral iridectomy is the most efficient method of treating this disease.

Münchener medicinische Wochenschrift, October 14, 1902.

Tendon Transplantation for a Paralyzed Quadriceps Femoris.—Magnus reports three cases in which good results were obtained. The method pursued was as follows: the insertions of the sartorius and biceps were freed, and the tendons of both these muscles drawn through a slit made in the tendon of the quadriceps, close to its union with the patella, and made fast to the tendon of the latter muscle. A plaster cast is applied, which is removed after six weeks. The results obtained by this method are interesting, in view of the fact that most authors regard tendon transplantation as of little avail in cases in which the quadriceps femoris is involved.

Pulmonary Œdema and Fibrinous Bronchitis Following Thoracentesis.—F. Magenau reports a rare case. The patient, following labor, had progressed favorably to the eighth puerperal day, when a left-sided pleurisy, with effusion developed. In spite of all treatment, the exudate increased rapidly in amount, and thoracentesis was performed, which resulted in the evacuation of a tolerably clear serous fluid, 2,500 c.c. in amount. Within a few hours thereafter a pulmonary œdema and fibrinous bronchitis set in. The case ran a course of nearly three months, ending in recovery. Careful observation was not able to determine a cause for these peculiar complications.

Sclerœdema.—A. Buschke reports a case in which this diagnosis was made. The patient was a male, forty-six years of age, and had just recovered from an attack of influenza. The first appearance of this peculiar condition was a stiffening of the skin of the back of the neck. This gradually extended until the entire neck and face were involved. Upon examination the skin was found to be swollen, and very tense, so that no lasting impression could be made by pressure, excepting upon the edges of the involved regions. Movements of the head and neck were painful, and the face had a peculiar mask-like expression. Although in many respects the case resembled one of sclerodermatitis it was evident, upon careful examination, that an infiltration was present in the deeper cutaneous structures. For this reason the term "sclerœdema" was applied. The case has now been under observation for two years. Under massage some improvement has taken place. The infiltration is, however, still present, although the movements of the head are less painful than formerly. The causation of the disease is unknown. Careful and repeated examinations have failed to reveal the presence of any kidney lesions.

Therapy and Pathogenesis of Stenocardia and Related Conditions.—Robert Breuer reviews the various theories relative to the pathogenesis of stenocardia, and comes to the conclusion that the primary cause is to be regarded as a pathological change in the arterial walls, as the result of which these vessels do not respond to the demand made upon them during bodily exercise. The result of this is an anæmia and weakness in the muscles supplied by the involved arteries. The subjective symptoms due to these conditions are pain and reduced functional activity in the muscles thus affected. A sharp differentiation is to be made between pseudo and true stenocardia. The former may be neurotic or reflective in origin, and is in no way associated with lesions of the arterial wall. The treatment resolves itself into two subdivisions: (1) Treatment of the attacks; (2) Treatment during the intervals. For the attacks morphine is the drug *par excellence*, although amyl-nitrite and nitroglycerine are often used with good results. During the intervals theobromine, or its various preparations, should be given. Much experience has demonstrated that this drug is superior to all others in its ability to lessen the frequency and the severity of the attacks. Observation has shown that there are a certain number of cases of indefinite abdominal pain which are due to lesions of the arterial walls of certain of the abdominal arteries, and which resist all ordinary treatment. If such cases are followed to the autopsy table, the arterial lesions mentioned will be found, and the pathogenesis of the condition made clear. In such cases, theobromine is very effective. The author has observed a number of such, a detailed description of which is given. Instances are also reported of the use of this drug in coronary angina, coronary angina with aortic insufficiency, coronary angina with aortic and mitral insufficiency, and coronary angina with aneurysm of the arch of the aorta. In all of these cases theobromine was very effective. Of the preparations of theobromine, diuretin is the one which seems to be the most effective. This should be given well diluted in a daily dose of 3 to 3.5 g. It is important that this amount should be equally divided throughout the twenty-four hours, so that the result may be continuous. Much has been said concerning the injurious effects of diuretin upon the stomach, and the annoying cerebral symptoms which often accompany its use. Breuer has never observed such, and believes that it may be given for long periods in the above dose with impunity. The mode of action of theobromine in this class of cases is not entirely clear, but it seems probable that it acts similarly to the nitrites as an arterial dilator. Its action, however, is much more powerful and lasting than the latter.

Münchener medicinische Wochenschrift, October 21, 1902.

Intestinal Action of Atropine.—Aronheim confirms Ostermaier's views, which have recently been published, concerning the favorable results obtained by the administration of atropine in hernias and other acute intestinal conditions. The author has used this drug with the best results in several cases of inflammation of the appendix. Here the daily subcutaneous dose was .001-.003. The local symptoms rapidly subsided, and the general condition improved in like ratio. Phenacetin, or antipyrin, were also given if high temperatures were present. A like result was obtained after the use of atropine in several cases of paralytic ileus.

Nature of the Circulatory Disturbances Accompanying Collapse in the Acute Infectious Diseases.—Passler and Rolly, after a series of extensive experimental observations upon rabbits, come to the conclusion that the primary cause of the circulatory disturbances which accompany collapse in the acute infectious diseases is to be found in a damaging to the vasomotor apparatus due to the toxins. Secondarily this leads to an inadequate supply of blood to the heart muscle, with its weakening and final collapse. The authors confined their observations to diphtheritic and pneumococcus infection. In diphtheria it is probable that the toxins, in addition to damaging the vasomotor apparatus, also exert a deleterious influence directly upon the heart muscle, but such is inconsiderate, and would lead to no serious consequences provided the vasomotor system remained intact. In pneumococcus infection, on the other hand, no injurious action of the toxins directly upon the heart muscle could be established. From these facts it is evident that in the treatment of the acute infectious diseases every effort should be made to sustain the action of the vasomotor apparatus.

Paratyphoid Fever.—F. M. G. de Feyfer and Heinrich Kayser report observations upon fourteen cases. Clinically, all of the cases were characterized by a short prodromal stage (one to four days) and a favorable course. The temperature curve was intermittent or remittent, and the frequency of the pulse corresponded thereto. Vomiting and diarrhœa were among the initial symptoms. The spleen was not palpable, but percussion frequently showed that it was slightly enlarged. A typical typhoid roseola was present in one-half of the cases. Bronchitis and angina were frequent complications. Intestinal hemorrhages were rare. The urine in all of the cases gave a positive diazo-reaction and showed the presence of a large amount of indican. In none of the cases save one did the blood serum of the patients agglutinate the bacillus typhosus. In this case the serum agglutinated both the bacillus typhosus and the bacillus paratyphosus (type B, Schottmüller). For this reason a diagnosis of a mixed infection (typhoid and paratyphoid) was here made. It is interesting to note that in this case the course was afebrile throughout. The blood serum of all the cases agglutinated the bacillus paratyphosus (type B, Schottmullen), but refused to agglutinate type A, isolated by the same author. In one case (the mixed infection) the serum was of very high agglutinating power, giving a positive reaction with type B in a 1 to 5,700 dilution. The agglutinating power of this serum was tested against certain other microorganisms with the following results: type A, 1-33 negative; bacillus typhosus, 1-120 positive; bacillus breslaviensis (Känsche), 1-720 positive; bacillus Gaustad (Holst), 1-360 positive; bacillus Backer (Holst), 1-33 negative, bacillus Morsellensis (von Ermenghen), 1-60 negative, bacillus Abel, 1-60 negative; bacillus morbificans bovis (Forster-Baseman), 1-60 positive; bacillus enteritidis (Gartner), 1-60 negative; bacillus Friedebergensis (Gaffky-Paak), 1-60 negative; bacillus paracoli (Kayser), 1-60 negative. The differential diagnosis of this disease comprises the differentiation between it and typhoid fever, the typhoid form of influenza, and a gastrointestinal catarrh with or without fever. This differentiation cannot be made upon clinical grounds, and is only to be determined as the result of agglutination tests.

French and Italian Journals.

Suprarenal Glycosuria.—Stefano Barba carried out a number of experiments with the view of ascertaining whether injections of suprarenal extract would cause glycosuria in human beings, as Blum, Zuelzer, Herter, and Richards claim that they do in animals. The result was negative, both in patients with normal suprarenal glands and in those suffering from Addison's disease. In one case of Addison's disease there was a slight aggravation of the general condition, and in the other two cases there was a general improvement and an increase in the diuresis.—*La Riforma Medica*, October 22, 1902.

A Saltless Diet and Its Effects on the Organism.—C. M. Belli instituted a series of researches with the view of ascertaining whether salt is really a necessity to life or not. He describes his investigations, and concludes therefrom that the absence of salt from the diet does not in any way affect the digestion nor the assimilation of food, but has a limited, though evident, influence on metabolism. This was accelerated if the salt were not added to the food, but returned to normal when the amount usually used was added. Salt is therefore not merely a condiment or a diuretic, but, according to the author, who quotes in support of his views Dubelir, Gabriel, Pugliese, Coggi, Straub, and Grube, it is an agent of nutritional economy.—*Annali di Medicina Navale*, September, 1902.

Two Cases of Musical Heart Sounds.—Modesto De Vivo describes two cases, and reviews the literature. He concludes that the causes of the phenomena may be various, such as tendinous bridles, inspissation and retraction of the cordæ tendineæ of the mitral valves, perforations, retractions of the valves, pericardial filaments, calcareous and fibrinous deposits which diminish the apertures of the blood vessel, diffuse atheroma, or, as in one of the cases described, a valve elongated by organized inflammatory deposits. The sounds are produced either by the vibration of these bridles and filaments, or by the vibration of the blood current against the calcareous or fibrinous deposits within the lumen of the aorta.—*La Riforma Medica*, October 14, 1902.

Ileocæcal Tuberculosis.—Guilbaud was called to attend a child that was said to be suffering from appendicitis. The incision revealed a large cæcum, very thick throughout its length. It was rigid, and of woody hardness. Its external surface was covered with tuberculous granulations. The terminal part of the ileum presented the same appearance, and the same consistence. The mesenteric ganglia were enormous. The appendix was behind the cæcum not visible. It was fixed in its position. There was no trace of suppurating focus, of false membrane, or of any walling off. It was then, not a case of local appendicitis with encysted peritonitis, but ileocæcal tuberculosis, of an hypertrophied and sclerosing form, with mesenteric adenopathy. The prognosis is always grave.—*Le Bulletin Médical*, October 18, 1902.

The Influence of the Micrococcus Tetragenus on the Tuberculous Process in the Lungs.—Alberto Michelazzi, from the results of his researches, reaches the following conclusions: (1) That the micrococcus tetragenus interferes with the development of the tubercular bacillus. (2) That when previously injected into a susceptible animal it prevents the development of tuberculosis not only in the lungs, but also in other organs. (3) If the tuberculous poison be first injected and then the micrococcus, there will be no interference with the development of tuberculosis. (4) The lesions produced by the micrococcus tetragenus in the lungs of guinea-pigs are precisely similar to tuberculous lesions in the human lungs (cavities, pneumonitis, etc.) and many of these lesions in man are to be ascribed to the action of the micrococcus.—*La Riforma Medica*, October 16, 17, 18, and 20, 1902.

Obligatory Medical Inspection of Workshops and Public Places in General.—Savoire states that the public authorities should institute obligatory medical inspection of workshops and public places. This is justified by the necessity of establishing early diagnosis of tuberculosis. The workmen should be taught the rules of antituberculous hygiene. The medical inspector should see that hygienic measures are instituted to assure the healthfulness of localities. After the medical examination the workmen should be classified according to their state of health. Those suspected of tuberculosis should be examined frequently till their definite condition is determined. The cases of tuberculosis should be isolated in every instance. The expenses of inspection should be borne by the aid societies.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 16, 1902.

The Endovenous Injection of Oxygen in Man.—C. Bernabei, while ackowledging the excellence of the experimental and practical work done by Mariani in the endovenous insufflation of oxygen in man, protests against the fact that no recognition has been given of his own preparatory and experimental work in the same direction. In his work on the extrapulmonary absorption (endovenous, subcutaneous, serous, and mucous) of gas (O, CO_2, N_2H_2, and, endovenous, for purposes of comparison, air), a work communicated to the Tenth Italian Congress of Internal Medicine, held in Rome in 1899, incorporated in the report of this congress and published in *Il Policlinico*, he had in mind the therapeutic application of the process. It would not have detracted, he thinks, from the value of Mariani's own admirable work to have referred to that previously done by a colleague.—*La Riforma Medica*, October 10, 1902.

Treatment of Tetanus.—Vallas discusses the properties of antitetanic serum. It is preventive if it is injected into the animal before, at the same time, or immediately after the toxin, especially if the injection is made ten or twelve hours before that of the toxin. Antitetanic serum, injected under the skin or into the blood, is incapable of curing or of attenuating confirmed tetanus. Immunity by injection of serum is acquired immediately after the injection, but lasts only a few days. The immunizing properties of serum last for a very long time. It does not prevent the vegetation of the bacillus of Nicolaier; it is not bactericidal. Its preservative action is due only to the destruction of the poison; it is only antitoxic. The antitoxin contained in the serum is not a modification of the injected toxin. It is a product of secretion of organic cells, probably of leucocytes, excited by the toxin. The antitetanic toxin is strongly agglutinating for a culture in bouillon of the bacillus of Nicolaier. The serum of a man cured of tetanus does not contain antitoxin. Besides, an attack of tetanus does not vaccinate against the disease.—*Gazette des Hôpitaux Civils et Militaires*, October 18, 1902.

Stenoses of the Pylorus.—Chauffard recognizes three principle causes of pyloric stenoses in the adult. There are stenoses of fibrous origin, of cancerous origin, and of spasmodic origin. In the first class the causes are various. There may be a scar of ulcerous origin, old inflammatory adhesions (peritonitis, syphilis), a congenital narrowing, and a sort of pyloric hypertrophy, as is noted sometimes in infants. The writer then describes several cases. The first patient was a man of thirty-five years, small and weak. He had suffered with his stomach since the age of fifteen. In order to decide on the best method of procedure, the exact dimensions of the dilatation of the stomach had to be estimated. This could be done by clapotage, by the study of the peristalsis of the stomach, by insufflation, and last and best of all, by illumination of the stomach by an electric lamp. Operation was decided upon, as the pylorus was found to be contracted. Gastroenterostomy was performed, and was followed by the happiest results till certain indiscretions in diet precipitated an ulcerous condition. A second operation was also successful, and the patient is in excellent condition, although he has to live very prudently.—*Journal des Praticiens*, October 18, 1902.

The Employment of Sterilized Linens in Nursing Infants.—Weill and Agniel call attention to the frequency of cutaneous infections (erythemas, pustules, furuncles, abscesses, etc.) in the children of the Crêches. For several years there was a veritable epidemic of affections of this nature at the Crêche de la Charité. The employment of antiseptic preparations in solutions or in the form of salves had been productive of no result. The medications even often produced irritating effects which aggravated the trouble. Powder had the best effect, but this was slight. The writers then conceived the idea of using sterilized cloth for dressing the children. From this moment there was a complete change. The children who had not been affected with the lesions remains unaffected, excepting at the point of the occiput, and the use of a sterilized cap caused this last lesion to disappear. All the surface of the body that was covered with the sterilized linen was protected against infection. With regard to the sick children, the results were still more remarkable. From the day when this treatment was begun, the cutaneous lesions ceased spreading and healed rapidly. In the specific infections (chickenpox and measles), the secondary infections were avoided by this treatment. In cases of ulceration, lymphangitis and erysipelas were prevented.—*Lyon Medical*, October 19, 1902.

Æsthetic Ablation of Benign Tumors of the Breast.—H. Morestin says that the blemish of a scar varies in importance according to the subject operated on, and according to the operation performed. As far as the breast is concerned, this question is of no importance to a large number of patients. Of recent years, the inconveniences of scars have been considerably decreased. They are far less disfiguring than was formerly the case. The immediate union, the care given to the wound, the perfection of the methods of suture, give results so satisfactory that surgeons may speak of "beautiful scars." The writer then describes his method of removing benign tumors of the breast without disfigurement. He operated on the first patient as follows. He made a very small high axillary incision. The incision measured 6 cm., and was in the hollow of the axilla. The next step was so to separate the tissues that a tunnel could be made from the incision to the tumor, which was in the lower, outer quadrant of the breast. For this maneuvring, a bistoury and scissors were used. The breast was held up as high as possible toward the place of incision, in order to shorten the distance as much as possible. When the tumor was reached, the capsule was opened with the scissors. Then long, thin forceps were thrust through the tunnel, and by them the tumor was seized and separated from its final attachments. The distance between the incision and the tumor was 15 cm., with the breast in normal position. A long drain was slipped into the axillomammary tunnel, under the loosened skin, and the skin was sutured. There was not a marked loss of blood. The wound was bandaged. The drain was withdrawn on the second day and the stitches on the sixth. The incision healed perfectly, and the scar had to be searched for to be seen. There was, of course, no mark on the breast.—*La Presse Médicale*, October 11, 1902.

A Case of Human Glanders, Ending in Recovery.—Charles Nicolle and Dubos declare that the observations of human glanders are not very numerous. The cases of recovery are exceptional. The writers then report a case which fell under their own observation. The patient was a young countryman. One day, when working in the fields, he felt the sensation of a foreign body in his left eye. He rubbed his eye vigorously with his hand. His father examined the eye, but saw nothing in it. The next day the patient felt a small, painless mass in front of the left ear. Two days later there was a large mass under and behind the jaw on the same side. The general condition was excellent. Twelve days later there appeared a third tumor of the same kind in the depths of the left calf. All of these masses increased rapidly in volume without any inflammatory phenomena or general reaction. The examination of two sick horses led the physician to think of glanders. Microscopical examination confirmed this diagnosis. The tumors were extirpated. This was followed by an amelioration, but recurrence soon took place. The removal was accomplished about a month after the first appearance of the infection. Medical treatment was instituted: forced feeding, rest, life in the open air, cacodylate of soda; but the disease was only arrested in its course. At the end of three months, when there was no appreciable result from the treatment, it was decided to inoculate the patient with the serum of a heifer. A total of 190 c.cm. were injected in two and one half months. From this moment the symptoms were rapidly ameliorated. The tumors disappeared, one after another. The ulcerations consecutive to the operation healed, and the small ganglionic masses that had developed in various parts of the organism disappeared spontaneously. The cure was complete before the end of the third month of treatment. It is now six months later and there has been no recurrence. The infection evidently took place through the conjunctiva.—*La Presse Medicale*, October 18, 1902.

Diagnosis of Cystic Disease of the Breast.—P. Bégouin reports two cases that have recently come under his notice, of cystic disease of the breast. One patient was a woman of fifty-four years, who six months before she presented herself at the hospital was struck in the breast. A small swelling developed gradually, without any pain and without any discharge from the nipple. It was difficult on looking at the breast to detect the swelling. The tumor felt like a round flat pebble with a diameter of about 5 cm. It was hard and [illegible]. The surface was lobulated, and irregular as if it were studded with grape-seeds. At the periphery, its limits were merged in the glandular tissue. Pressure on the tumor did not cause any discharge from the nipple. The skin over the tumor was movable, and also over the pectoral muscle. There was a small gland high up in the axilla without any special characteristic. The second case described had essentially the same characteristics. Several points would suggest cancer, such as the age, the rapid development, the hardness, the irregular surface, and the indistinct limits of the growth. But, as in all cases of cystic disease, there was no sign at the beginning to call attention to the diagnosis of cancer. The cases both proved to be cystic disease of the breast. In both cases were found nodosities in the neighborhood of the tumor and in the other breast. The writer adds that in every case of tumor of the breast, that might be taken for cancer, although this diagnosis is not evident, it is always necessary to examine the part of the gland which appears healthy as well as the other breast. If there are disseminated nodosities, even though scarcely appreciable, the disease of Reclus must be thought of, and its diagnosis eliminated or confirmed. Before operation, an exploratory puncture should be made, and, if there is still doubt, an exploratory incision. These preparatory precautions will determine that a certain number of so-called cancers are only cystic disease. The cystic disease is almost always bilateral, and tiny nodosities are found in the neighborhood of the tumor and in the opposite breast.—*Journal de Médecine de Bordeaux*, October 19, 1902.

Revue de Medicine, October, 1902.

Arterial Hemorrhagic Changes in Cirrhosis.—Ch. Bouchard says that abdominal plethora is not the only cause of hemorrhages of the digestive tract in cirrhosis. Certainly hemorrhages which occur outside of the territory of the portal vein, and which are very frequent in cirrhosis cannot be due to this cause. They are in relation with preexisting arterial lesions affecting the skin, the mucous membrane of the mouth, the pharynx, and the œsophagus. The gastrorrhagias of cirrhosis are also due to a preexisting arterial lesion. Epistaxis from arterial lesion is in intimate connection with cirrhosis.

Anguish.—Paul Londe considers anguish to be a symptom which is both mental and somatic. It may result from any perturbation of psychic or organic life, the perturbation being transmitted to the bulb. The manifestation of the symptom is sometimes merely a simple malaise, but it may be psychic, and there may even be delirium. It is accompanied by various bulbar troubles; it may be masked or abortive. It is always more or less paroxysmal, yet there have been described cases of chronic states of anguish with recrudescence. Cheyne-Stokes' respiration induces a sort of chronic anguish. In the diagnosis we should attempt to recognize the syndrome under the most varied aspects, to ascertain its origin, and to decide whether there be a lesion or merely a functional trouble.

Revue de Chirurgie, October, 1902.

Massage of the Exposed Heart.—Maurice Boureau says that the experiments made in the direction of giving massage to the exposed heart in case of syncope have so far given no decisive results. In cases of chloroform syncope, his advice is to first apply Sylvester's method of artificial respiration which is nearly always sufficient to restore the patient, and then to try rhythmical tractions of the tongue. If, after ten minutes of these manœuvres, respiration does not return, then, as a last resort, the surgeon might make a diaphragmatic incision, and give massage to the heart. The author, however, has no very great faith in the procedure, and thinks that it will probably be abandoned by surgeons before long.

The Scattering of Hydatid Cysts by Operation.—F. Devé concludes from his experimentation that the scolex and the proligerous capsules (specific microscopic germs), as well as the daughter vesicles (macroscopic elements), can give rise to new hydatid cysts. During the course of bloody operations on hydatid cysts the greatest care should be taken to prevent the dissemination of the infection outside of the sac, and to destroy the various specific germs contained within the parasitic vesicle in the interior of the sac. Experimentally, a 1 per 1,000 solution of bichloride or a 1 to 200 of formol will, in from two to two and a half minutes, destroy the vitality of the hydatid germs. In the case of non altered cysts, a preliminary parasiticidal injection of Van Swieten's fluid, or better, of formol, 1 to 200, left two or three minutes in contact with the contents of the mother vesicle, will, apparently, prevent the formation of post-operative echinococcosis.

Society Reports.

CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA.

Proceedings of the Seventeenth Annual Meeting, Held at New Haven, Conn., October 28 and 29, 1902.

The conference convened in North Sheffield Hall, under the Presidency of Dr. H. M. Bracken of Minneapolis, Minn.

Report of the Committee on Communicable Diseases.—Dr. B. Stanton of Cincinnati, Ohio, in the absence of the chairman, presented the report of this committee. The following list of diseases believed to be communicable, dangerous to the public health, and such as boards of health may properly endeavor to prevent, was presented: Typhoid fever, typhus fever, smallpox, chickenpox, measles, scarlet fever, whooping cough, diphtheria, influenza, cholera, yellow fever, bubonic plague, mumps, German measles, glanders, hydrophobia, malaria, epidemic cerebrospinal meningitis, pneumonia, puerperal fever, epidemic dysentery, erysipelas, beriberi, ankylostomiasis, leprosy, tetanus, anthrax, actinomycosis, trichinosis, trachoma, scabies, syphilis, and gonorrhœa. After considerable discussion this report was adopted. The conference discussed and adopted a new constitution.

Production and Control of Vaccine Virus and Antitoxins.—Dr. U. O. B. Wingate of Milwaukee, Wis., spoke on this subject, discussing it under six headings, as follows: (1) Does the commercial element relative to vaccine virus, antitoxin, etc., render these agents dangerous for use? If so, what course should be pursued to eliminate commercialism? (2) Should the nation or State control the production and sale of same? (3) If the nation should control it, should its production and distribution be under the supervision of the Public Health and Marine Hospital service of the United States? (4) It is practicable for State boards of health to institute inspections over the production and sale of these agents, and should State boards propagate these agents? (5) Does not the commercial element threaten the public confidence, and if some steps are not taken, can we maintain the reputation that a proper use of these agents fully merits? (6) Should humanized vaccine virus be used in preference to bovine virus?

He thought the first and fifth should be considered jointly. His experience had been sufficient during the present epidemic of smallpox in this country to furnish a certain amount of information concerning the subject which was of great value. In his experience there had been considerable difficulty with the vaccine virus. Too much trouble resulted from its use. Whenever an outbreak of smallpox occurred, it was quite a serious thing to get a supply of virus to use and then find it had no effect, and that those who were exposed, who might be protected by successful vaccination, were not protected because the virus was impure. This had occurred in a number of cases. He thought some measure should be taken whereby, if vaccination was urged, a sufficient amount of protection would be given to the public, so as to obtain its confidence.

In regard to antitoxin, he thought this could possibly be excluded. Perhaps the commercial element did not enter into this question so much as it did in that of vaccine virus. He quoted from Theobald Smith, who said (referring to these products) the preparation of animal vaccine is simple enough, and its simplicity is a source of danger, because its production may be undertaken by such as are not sufficiently trained in scientific methods to apprehend and utilize the improvements brought about by investigation as well as anticipase and guard against the dangers due to altered conditions. In this regard vaccine virus differs from the preparation of diphtheria antitoxin, because the latter substance cannot be prepared excepting by those who have had considerable technical training. Its successful manufacture necessarily implies that degree of care which also assures the safety of the product.

If this were true, the essayist said, it would relieve us very much in regard to the manufacture and sale of antitoxin. The greatest danger was in the production of these products, and not in the actual sale of them.

Regarding the other divisions of the subject, he again quoted from Theobald Smith, with reference to inspection, etc., and the practice that existed on the continent. Each State or State division assumed the responsibility of preparing the vaccine virus itself, and the national government appointed inspectors, provided vaccine plants, under whose supervision the virus was prepared, tested, and officially stamped, the same being done with regard to antitoxin in Germany.

As we had now a national public health organization well equipped with experts, Dr. Wingate thought it would be practicable to have agents appointed to inspect the products of vaccine virus, and perhaps the other products, or some means might be adopted by which we could say to the public that these products were safe to use, and that they were efficacious. He did not think this could be said now of these products at all times. He believed that any recommendations which might emanate from the conference would have considerable influence in establishing a system of this kind.

Massachusetts had been producing its own antitoxin for a number of years, with good results. The State Board of Health produced it, and supplied antitoxin free to those who applied for it throughout the State. Whether other States could do this generally or not was a question. It was certainly a step in the right direction, because if antitoxin was prepared under the supervision of the State Board of Health it would be done properly. Furthermore, a great majority of people who required antitoxin were poor. They could not avail themselves of the remedy if they had to purchase it in order to use it. Whether the State or the local health authorities should furnish it was a question, so far as the expense was concerned. In some localities in his State the laws were such that the expense of these agents would be put upon the county, town, village, or city, and the State was appealed to in extreme cases. He thought it would be difficult in Wisconsin to secure the passage of laws whereby antitoxin could be supplied for the use of those who might apply for it to the State Board of Health.

Some Questions to Be Answered in Dealing with Smallpox.—Dr. C. O. Probst of Columbus, Ohio, followed with this paper. He stated that in Ohio, since the present epidemic began, 14,224 cases of smallpox had been reported, with 376 deaths. This was probably considerably short of the actual number of cases, for many had doubtless occurred that were never recognized or reported as smallpox. Even now, when the disease made its appearance in a new neighborhood, disputes in diagnosis often occurred. The main difficulty at present was from the people, especially the merchants, who were unwilling to accept the diagnosis of smallpox made by the local physicians. The State Board of Health of Ohio had appointed ten experienced physicians as medical inspectors, paying them $10.00 a day and expenses. When the diagnosis of smallpox was made locally, the board insisted that the local authorities should accept it, and if they called upon the State Board to send some one to verify the diagnosis, the local authorities were made to pay the expense. Should the State or community pay this expense? The community usually receives the greater part of the benefit. A prompt diagnosis might prevent an epidemic. If the disease was not recognized as smallpox, or not treated as such, it was carried to other, perhaps quite distant, communities. A proper line should be drawn between State and local responsibility in these cases. His conclusions were:

The State should make an inspection and pay the expenses thereof: (1) When the attending physician, with the help of local counsel, if obtainable, is uncertain of the diagnosis. (2) When there is a serious dispute among local physicians as to the character of the disease. It often happens that there is one or more physicians in a place who, perhaps without seeing the case, publicly declares the disease is not smallpox. They will usually say so after the State inspector has pronounced it smallpox, and they should not be regarded in deciding the question of sending an inspector. (3) When an eruptive contagious disease, affecting adults, is prevailing, and not considered or treated as smallpox. (4) When the local board of health requests advice in enforcing restrictive measures, or where complaint is made and there is reason to believe that such board is neglecting its duties, and matters cannot be settled by telephone or letter. Exceptional cases other than these may arise, when the State should send and pay the inspector.

The community should pay this expense (1) When the attending physician diagnoses the case as smallpox. (2) When the attending physician is in doubt, and the board of health is unwilling to call competent local counsel, simply to escape paying a consultation fee. (3) When the character of an outbreak has been fully established, and other cases, directly traceable to known cases of smallpox, are the subject of dispute, and the symptoms indicate smallpox.

The next question he considered was that of control of interurban quarantine. Should the State Board of Health have authority to modify or set aside a local quarantine regulation? Yes, but it should use this power in urgent cases only.

He presented a plan whereby a State board of health might possibly give reasonable assurance of purity of vaccine virus. The Ohio board contemplated putting such a plan into operation, and was holding it in abeyance, hoping to have it criticised at this meeting. Two vaccine propagators, and a third might be added, were willing to enter into this arrangement. They would furnish once a month, or as often as necessary, samples of two or three lots of vaccine virus. The size of a lot would depend on the general demand, and might be the product of one heifer, or the mixed product of several inoculated on the same day. The lots would be numbered. A sample of each lot would be examined for the number of bacteria and presence of pus organisms. Possibly a test would be made for the tetanus bacillus The methods of examination would be published, and when the sample passed muster, it would be announced that lot so-and-so produced by such-and-such propagator, had been examined, and the sample had been found free from pathogenic organisms. The propagator on his side would agree that any person in Ohio ordering virus of a particular lot should receive that virus and no other, unless notified to the contrary. He would not be bound to hold this virus especially for the Ohio trade, to his loss, but would endeavor to keep a supply of it on hand.

This plan had suggested itself to the board of Ohio because of the great opposition to vaccination, occassioned largely by the lack of public confidence in the purity of commercial vaccine. The exaggerated statements of the bad results from vaccine in Cleveland, and the reports of several deaths there from tetanus credited to vaccination even by the medical profession, made it highly desirable that the people of Ohio should in some way be given assurance of the purity of virus used.

Dr. **Samuel W. Abbott** of Wakefield, Mass., in opening the discussion on these two papers, stated that the State Board of Health of Massachusetts had examined the products of several private producers of antitoxin in 1896, as sold in the open market, and found some of them absolutely worthless. Speaking of the experience of his own State in antitoxin production, he said (1) about 180,000 packages had been produced in the nearly eight years of production up to the present date. (2) Nearly one-quarter of a million dollars had been saved to the State, the principal portion of which would have gone out of the State to private producers. (3) Several thousand lives had been saved which might otherwise have been lost through inability to pay the cost of life-saving. (4) No untoward accidents or injuries had been reported in the State from the use of antitoxin in the eight years (5) All parties were absolutely satisfied with State production, including the physicians and boards of health who used the product, and the people for whose benefit it was used. No one was discontented except the few who desired a change for commercial reasons only.

Dr. **Walter Wyman**, Surgeon-General of the Marine Hospital service, called attention to a bill which was presented at the last session of Congress entitled, "An Act to Regulate the Sale of Viruses, Serums, Toxins, and Analogous Products in the District of Columbia, to Regulate Interstate Traffic in Said Articles, and for Other Purposes." The number of this bill is 244.

Dr. **H. D. Geddings** of Washington, D. C., said that the question of antitoxins should be approached from two standpoints. There must be assurance that the public or the consumer should guard against such distressing and fatal results as had attended the late much-exploited cases in St. Louis. Up to the time of the occurrence of those cases the possibility of such accidents was recognized, but had not received the careful attention that it might have. Since that time, it had been claimed by every manufacturer of antitoxin that he specifically tested his product to see that it contained neither the organisms of tetanus nor the toxins produced by that organism.

The public in buying antitoxin was entitled, in equity and in justice, to receive what it paid for as advertised upon its labels. To sell a serum represented to contain two thousand antitoxin units to the cubic centimeter, and which was shown on test to fall between one thousand and two thousand, was certainly delivering goods under false pretences. He did not believe that it would be possible for national authority, as at present constituted, to exercise the function of inspection over all the antitoxin that was produced. It would be an operation of tremendous magnitude. The amount of serum antitoxin produced in the United States was large. However, some such control should be exercised, and was exercised in Germany, Italy, England, and France.

In regard to vaccine virus, if there was upon the market to-day a truly antiseptic, aseptic, or germ-free vaccine virus, the Hygienic Laboratory of Public Health of the Marine Hospital service was not able to purchase it in open market. Samples of every virus obtainable were submitted to tests in the hygienic laboratory, the result of these examinations showing that none was truly aseptic or antiseptic, and that none was germ-free.

Speaking of glycerinized lymph, he thought too much reliance had been placed upon the alleged antiseptic property of glycerin. A series of experiments conducted in the hygienic laboratory showed conclusively that while glycerin was to a certain extent a preservative of considerable potency, it was far from being an antiseptic or a germicide. The point he made was that the glycerinizing of the lymph could not take the place of scrupulous care in the original preparation of the material. If due antiseptic and aseptic precautions were exercised in gathering the lymph, it was possible that the addition of glycerin was unnecessary On the other hand, if it was gathered carelessly, proper precautions not being taken the addition of any amount of glycerin up to 100 per cent would not affect the sterilization of the product.
